Syntax Repair as Language Intersection

ANONYMOUS AUTHOR(S)

We introduce a new technique for correcting syntax errors in arbitrary context-free languages. Our work stems from the observation that syntax errors with a small repair typically have very few unique small repairs, which can usually be enumerated up to a small edit distance then quickly reranked. We place a heavy emphasis on precision: the enumerated set must contain every possible repair within a few edits and no invalid repairs. To do so, we model error correction as a language intersection problem between a Levenshtein automaton and a context-free grammar. To extract the repairs, we sample trees from the intersection grammar, yielding valid repairs within a certain Levenshtein distance. Finally, we rank those repairs by n-gram likelihood.

1 INTRODUCTION

Syntax errors are a familiar nuisance for programmers, arising due to a variety of factors, from inexperience, typographic error, to cognitive load. Often the mistake itself is simple to fix, but manual correction can disrupt concentration, a developer's most precious and fickle resource. Syntax repair attempts to automate the correction process by modifying a syntactically invalid program so that it conforms to the grammar, saving time and attention.

Early work on syntax repair by Irons [25] and Aho [2] use techniques from dynamic programming to find the nearest parse trees for an erroneous input. These methods guarantee correctness, but do not attempt to completely recover all nearby corrections, but instead find just one or a small number of corrections, which are not necessarily the most likely or natural repairs. Nevertheless, these methods are appealing for their interpretability and well-understood algorithmic properties.

More recently, probabilistic repair techniques have been introduced using neural language models to predict the most likely correction [3, 36, 41]. While these techniques generate far more natural edits, they are often costly to train, prone to misgeneralization, and difficult to incorporate new constraints thereafter. Furthermore, the generated repairs are not necessarily sound without additional filtering, and we observe the released models often hallucinate false positive repairs.

Recent work by Merrill et al. [30] and Chiang et al. [13] suggest that the issue may be more foundational: transformer-based language models, a popular class of neural language models used in probabilistic program repair, are fundamentally less expressive than context-free grammars, which formally describe the syntax of most programming languages. This suggests such models, despite their useful approximation properties, are ill-suited for the task of end-to-end syntax repair. Yet, they may still be useful for resolving ambiguity between valid repairs of differing likelihood.

In this work, we consider the problem of ranked syntax repair under finite Levenshtein bounds. We demonstrate it is possible to attain a significant advantage over state-of-the-art neural repair techniques by exhaustively retrieving every valid Levenshtein edit in a certain distance and scoring it. Not only does this approach guarantee both soundness and completeness, we find it also improves precision when ranking by naturalness. Our proposed solution is straightforward:

(1) We model syntax repair as a language intersection problem between the Levenshtein ball and a context-free language, then materialize the grammar using a specialized version of the Bar-Hillel construction to Levenshtein intersections. (§ 4.3)
(2) We construct a data structure via idempotent matrix completion that compactly represents parse forests in context-free languages. This data structure is used to index syntax trees, significantly reducing the size of the intersection grammar. (§ 4.4, 4.5)

SPLASH'24, October 22-27, 2024, Pasadena, California, United States
2024. ACM ISBN 978-x-xxxx-xxxx-x/YY/MM…$15.00
https://doi.org/10.1145/nnnnnnn.nnnnnnn

(3) To extract the repairs, primarily we sample trees without replacement by constructing an explicit bijection between syntax trees and integers, sample integers uniformly without replacement from a finite range, then decode them as trees. (§ 4.5)
(4) Finally, we rerank all repairs found before a fixed timeout by n-gram likelihood. (§ 4.6)

Our primary technical contributions are threefold: (1) the adaptation of the Levenshtein automaton and Bar-Hillel construction to syntax repair (2) a theoretical connection between idempotent matrix completion and CFL parsing with holes, and (3) an algebraic datatype and integer bijection for enumerating or sampling valid sentences in context-free languages. The efficacy of our technique owes to the fact it does not synthesize probable edits, but unique, fully formed repairs within a certain edit distance. This enables us to suggest correct and natural repairs with far less compute and data than would otherwise be required by a large language model to attain the same precision.

2 EXAMPLE

Syntax errors are usually fixable with a small number of edits. If we assume the intended repair contains just a few edits, this imposes strongly locality constraints on space of possible edits. For example, let us consider the following Python snippet, which contains a small syntax error:

```
def prepend(i, k, L=[]) n and [prepend(i - 1, k, [b] + L) for b in range(k)]
```

We can fix it by inserting a colon after the function definition, yielding:

```
def prepend(i, k, L=[]): n and [prepend(i - 1, k, [b] + L) for b in range(k)]
```

A careful observer will note that there is only one way to repair this Python snippet by making a single edit. In fact, many programming languages share this curious property: syntax errors with a small repair have few uniquely small repairs. Valid sentences corrupted by a few small errors rarely have many small corrections. We call such sentences *metastable*, since they are relatively stable to small perturbations, as likely to be incurred by a careless typist or novice programmer.

Let us consider a slightly more ambiguous error: `v = df.iloc(5:, 2:)`. Assuming an alphabet of just a hundred lexical tokens, this tiny statement has millions of possible two-token edits, yet only six of those possibilities are accepted by the Python parser:

(1) `v = df.iloc(5:, 2,)` (3) `v = df.iloc(5[:, 2:])` (5) `v = df.iloc[5:, 2:]`

(2) `v = df.iloc(5), 2()` (4) `v = df.iloc(5:, 2:)` (6) `v = df.iloc(5[:, 2])`

With some typing information, we could easily narrow the results, but even in the absence of semantic constraints, one can probably rule out (2, 3, 6) given that `5[` and `2(` are rare bigrams in Python, and knowing `df.iloc` is often followed by `[`, determine (5) is most natural. This is the key insight behind our approach: we can usually locate the intended fix by exhaustively searching small repairs. As the set of small repairs is itself often small, if only we had some procedure to distinguish valid from invalid patches, the resulting solutions could be simply ranked by naturalness.

The trouble is that any such procedure must be highly sample-efficient. We cannot afford to sample the universe of possible d-token edits, then reject invalid samples – assuming it takes just 10ms to generate and check each sample, (1-6) could take 24+ hours to find. The hardness of brute-force search grows superpolynomially with edit distance, sentence length and alphabet size. We will need a more efficient procedure for sampling all and only small valid repairs.

3 PROBLEM STATEMENT

Source code in a programming language can be treated a string over a finite alphabet, Σ. We will use a lexical alphabet for convenience. The language has a syntax, $\ell \subset \Sigma^*$, containing every acceptable program. A syntax error is an unacceptable string, $\underset{\sim}{\sigma} \notin \ell$. We can model syntax repair as a language intersection between a context-free language (CFL) and a regular language. Henceforth, $\underset{\sim}{\sigma}$ will always and only be used to denote a syntactically invalid string whose target language is known.

Definition 3.1 (Bounded Levenshtein-CFL reachability). Given a CFL, ℓ, and an invalid string, $\underset{\sim}{\sigma} : \ell^{\complement}$, find every valid string reachable within d edits of $\underset{\sim}{\sigma}$, i.e., letting Δ be the Levenshtein metric and $L(\underset{\sim}{\sigma}, d) = \{\sigma' \mid \Delta(\underset{\sim}{\sigma}, \sigma') \leq d\}$ be the Levenshtein d-ball, we seek to find $A = L(\underset{\sim}{\sigma}, d) \cap \ell$.

As the admissible set A is typically under-constrained, we want a procedure which surfaces natural and valid repairs over unnatural but valid repairs:

Definition 3.2 (Ranked repair). Given a finite language $A = L(\underset{\sim}{\sigma}, d) \cap \ell$ and a probabilistic language model $\mathrm{P}_\theta : \Sigma^* \to [0, 1] \subset \mathbb{R}$, the ranked repair problem is to find the top-k maximum likelihood repairs under the language model. That is,

$$R(A, P_\theta) = \underset{\boldsymbol{\sigma} \subseteq A, |\boldsymbol{\sigma}| \leq k}{\operatorname{argmax}} \sum_{\sigma \in \boldsymbol{\sigma}} \mathrm{P}_\theta(\sigma \mid \underset{\sim}{\sigma}) \tag{1}$$

A popular approach to ranked repair involves learning a distribution over strings, however this is highly sample-inefficient and generalizes poorly to new languages. Approximating a distribution over Σ^* forces the model to jointly learn syntax and stylometry. Furthermore, even with an extremely efficient approximate sampler for $\sigma \sim \ell_\cap$, due to the size of ℓ and $L(\underset{\sim}{\sigma}, d)$, it would be intractable to sample either ℓ or $L(\underset{\sim}{\sigma}, d)$, reject duplicates, then reject invalid ($\sigma \notin \ell$) or unreachable ($\sigma \notin L(\underset{\sim}{\sigma}, d)$) edits, and completely out of the question to sample $\sigma \sim \Sigma^*$ as do many neural language models.

As we will demonstrate, the ranked repair problem can be factorized into a bilevel objective: first maximal retrieval, then ranking. Instead of working with strings, we will explicitly construct a grammar which soundly and completely generates the set $\ell \cap L(\underset{\sim}{\sigma}, d)$, then retrieve repairs from its language. By ensuring retrieval is sufficiently precise and exhaustive, maximizing likelihood over the retrieved set can be achieved with a much simpler, syntax-oblivious language model.

Assuming we have a grammar that recognizes the Levenshtein-CFL intersection, the question then becomes how to maximize the number of unique valid sentences in a given number of samples. Top-down incremental sampling with replacement eventually converges to the language, but does so superlinearly [21]. Due to practical considerations including latency, we require the sampler to converge linearly, ensuring with much higher probability that natural repairs are retrieved in a timely manner. This motivates the need for a specialized generating function. More precisely,

Definition 3.3 (Maximal retrieval). Given a CFL, ℓ, we want a randomized generating function, $\boldsymbol{\varphi} : \mathbb{N}_{<|\ell|} \to 2^\ell$, whose rate of convergence is linear in expectation, i.e., $\mathbb{E}_{i \in [1,n]} |\boldsymbol{\varphi}(i)| \propto n$.

To satisfy Def. 3.3, we construct a bijection between syntax trees to integers (§ 4.5), sample integers uniformly without replacement, then decode them as trees. This will produce a set of unique trees, and each tree, assuming grammatical unambiguity, will correspond to a unique sentence in the language. As long as $|\ell_\cap|$ is sufficiently small and enough samples are drawn, $\boldsymbol{\varphi}$ is sure to include the most natural repairs, and additionally, will terminate after exhausting all sentences.

Finally, once we have a set of small and valid repairs, the problem of ranked repair reduces to sorting retrieved samples by likelihood, which can be approximated using an autoregressive language model or any suitable scoring function of the implementer's choice. In our case, we use a low-order Markov model for its inference speed, data efficiency, and simplicity.

4 METHOD

The method we describe in this paper takes as input the invalid code fragment, and returns a set of plausible repairs. We assume to know the target syntax and a low-rank distribution of lexical n-grams to estimate the likelihood of candidate repairs. At a high level, our method can be decomposed into three main steps: (1) language intersection, (2) repair extraction, and (3) reranking.

First, we generate a synthetic grammar representing the intersection between the syntax and the Levenshtein ball around the source code. During extraction, we retrieve as many repairs as possible from the intersection grammar via sampling or enumeration. Finally, in the reranking step, we rank all repairs by n-gram likelihood. This can be depicted in more detail as a flowchart (Fig. 1).

Since the syntax of most programming languages is context-free, we first construct a context-free grammar (CFG), $G_\cap$, that represents the intersection between the language's syntax (G) and an automaton recognizing the Levenshtein ball of a given radius, $L(\underset{\sim}{\sigma}, d)$. As the CFL family is closed under intersection with regular languages, this is admissible. Three outcomes are possible:

(1) $G_\cap$ is empty, in which case there is no repair within the given radius. In this case, we simply increase the radius and try again.
(2) $\mathcal{L}(G_\cap)$ is small, in which case we enumerate all possible repairs. Complete enumeration is tractable for the majority of all syntax repairs.
(3) $\mathcal{L}(G_\cap)$ is too large to completely enumerate, so we sample instead from $G_\cap$, top-down. Sampling is necessary for a minority of remaining cases.

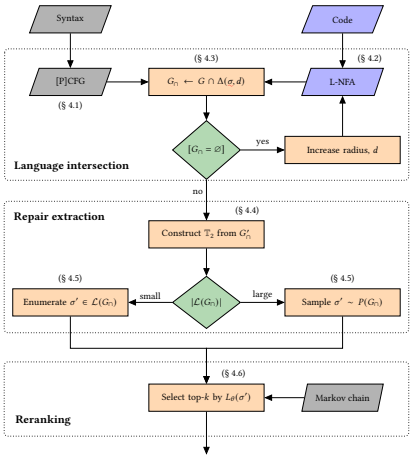

Fig. 1. Dataflow of our proposed method.

As long as we have done our job correctly, the intersection language should contain every plausible repair within a certain Levenshtein distance, and no invalid repairs. We will first describe how to generate the intersection grammar (§ 4.2, 4.3), then, describe a data structure compactly representing its language, allowing us to efficiently extract all repairs contained within (§ 4.5). Finally, we use an n-gram model to rank and return the top-k results by likelihood (§ 4.6).

4.1 Preliminaries

Recall that a CFG, $\mathcal{G} = \langle \Sigma, V, P, S \rangle$, is a quadruple consisting of terminals (Σ), nonterminals (V), productions ($P \colon V \longrightarrow (V \mid \Sigma)^*$), and a start symbol, ($S$). Every CFG is reducible to so-called *Chomsky Normal Form*, $P' \colon V \longrightarrow (V^2 \mid \Sigma)$, where every production is either (1) a binary production $w \longrightarrow xz$, or (2) a unit production $w \longrightarrow t$, where $w, x, z : V$ and $t : \Sigma$. For example:

$$G = \{\, S \longrightarrow S\,S \mid (\,S\,) \mid (\,) \,\} \Longrightarrow G' = \{\, S \longrightarrow Q\,R \mid S\,S \mid L\,R, \quad R \longrightarrow), \quad L \longrightarrow (, \quad Q \longrightarrow L\,S \,\}$$

Likewise, a finite state automaton is a quintuple $\mathcal{A} = \langle Q, \Sigma, \delta, I, F \rangle$, where Q is a finite set of states, Σ is a finite alphabet, $\delta \subseteq Q \times \Sigma \times Q$ is the transition function, and $I, F \subseteq Q$ are the set of initial and final states, respectively. We will adhere to this notation in the following sections.

4.2 Modeling lexical edits with the nominal Levenshtein automaton

Levenshtein edits are recognized by an automaton known as the Levenshtein automaton. As the original construction defined by Schultz and Mihov [37] contains cycles and ε-transitions, we propose a variant which is ε-free and acyclic. Furthermore, we adopt a nominal form which supports infinite alphabets and considerably simplifies the language intersection to follow. Illustrated in Fig. 2 is an example of a small Levenshtein automaton recognizing $L(\sigma : \Sigma^5, 3)$. Unlabeled arcs accept any terminal from the alphabet, Σ. Equivalently, this transition system can be viewed as a kind of proof system within an unlabeled lattice. The following construction is equivalent to Schultz and Mihov's original Levenshtein automaton, but is more amenable to our purposes as it does not any contain ε-arcs, and instead uses skip connections to recognize consecutive deletions of varying lengths.

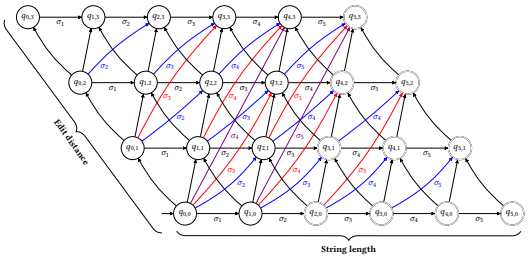

Fig. 2. NFA recognizing Levenshtein $L(\sigma : \Sigma^5, 3)$.

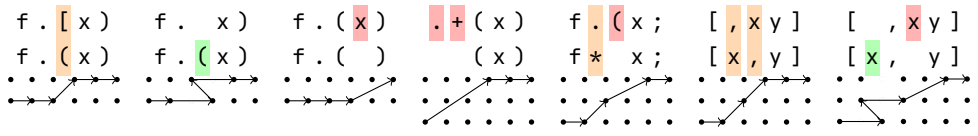
$$\frac{s \in \Sigma \quad i \in [0, n] \quad j \in [1, d_{\max}]}{(q_{i,j-1} \xrightarrow{s} q_{i,j}) \in \delta} \qquad \frac{s \in \Sigma \quad i \in [1, n] \quad j \in [1, d_{\max}]}{(q_{i-1,j-1} \xrightarrow{s} q_{i,j}) \in \delta}$$

$$\frac{i \in [1, n] \quad j \in [0, d_{\max}]}{(q_{i-1,j} \xrightarrow{\sigma_i} q_{i,j}) \in \delta} \qquad \frac{d \in [1, d_{\max}] \quad i \in [d+1, n] \quad j \in [d, d_{\max}]}{(q_{i-d-1,j-d} \xrightarrow{\sigma_i} q_{i,j}) \in \delta}$$

$$\frac{}{q_{0,0} \in I}\ \textsc{Init} \qquad \frac{q_{i,j} \qquad |n - i + j| \le d_{\max}}{q_{i,j} \in F}\ \textsc{Done}$$

Each arc plays a specific role. ↖ handles insertions, ↗ handles substitutions and ⋰ handles deletions of one or more terminals. Let us consider some illustrative cases.



Note that the same patch can have multiple Levenshtein alignments. Done constructs the final states, which are all states accepting strings σ' whose Levenshtein distance $\Delta(\sigma, \sigma') \le d_{\max}$.

To avoid creating a parallel bundle of arcs for each insertion and substutition point, we instead decorate each arc with a nominal predicate, accepting or rejecting σ_i. To distinguish this nominal variant from the original construction, we highlight the modified rules in orange below.

$$\frac{i \in [0, n] \quad j \in [1, k]}{(q_{i,j-1} \xrightarrow{[\neq \sigma_i]} q_{i,j}) \in \delta} \qquad \frac{i \in [1, n] \quad j \in [1, k]}{(q_{i-1,j-1} \xrightarrow{[\neq \sigma_i]} q_{i,j}) \in \delta}$$

$$\frac{i \in [1, n] \quad j \in [0, k]}{(q_{i-1,j} \xrightarrow{[= \sigma_i]} q_{i,j}) \in \delta} \qquad \frac{d \in [1, d_{\max}] \quad i \in [d+1, n] \quad j \in [d, k]}{(q_{i-d-1,j-d} \xrightarrow{[= \sigma_i]} q_{i,j}) \in \delta}$$

Nominalizing the NFA eliminates the creation of $e = 2(|\Sigma| - 1) \cdot |\sigma| \cdot d_{\max}$ unnecessary arcs over the entire Levenshtein automaton and drastically reduces the size of the construction to follow, but does not affect the underlying semantics. Thus, it is essential to first nominalize the automaton before proceeding to avoid a large blowup in the intermediate grammar.

4.3 Recognizing syntactically valid edits via language intersection

We now describe the Bar-Hillel construction, which generates a grammar recognizing the intersection between a regular and a context-free language, then specialize it to Levenshtein intersections.

Lemma 4.1. *For any context-free language ℓ and finite state automaton α, there exists a context-free grammar $G_\cap$ such that $\mathcal{L}(G_\cap) = \ell \cap \mathcal{L}(\alpha)$. See Bar-Hillel [5].*

Although Bar-Hillel [5] lacks an explicit construction, Beigel and Gasarch [8] construct $G_\cap$ like so:

$$\frac{q \in I \quad r \in F}{(S \to qSr) \in P_\cap} \qquad \frac{(A \to a) \in P \qquad (q \xrightarrow{a} r) \in \delta}{(qAr \to a) \in P_\cap} \qquad \frac{(w \to xz) \in P \qquad p,q,r \in Q}{(pwr \to (pxq)(qzr)) \in P_\cap} \bowtie$$

This, now standard, Bar-Hillel construction applies to any CFL and REG language intersection, but generates a grammar whose cardinality is approximately $|P_\cap| = |I|\cdot|F|+|P|\cdot|\Sigma|\cdot|\sigma|\cdot 2d_{\max}+|P|\cdot|Q|^3$. Applying the BH construction directly to practical languages and code snippets can generate hundreds of trillions of productions for even modestly-sized grammars and Levenshtein automata. Instead, we will describe a kind of reachability analysis that elides many superfluous productions in the case of Levenshtein intersection, greatly reducing the size of the intersection grammar, $G_\cap$.

Consider $\bowtie$, the most expensive rule. What $\bowtie$ tells us is each nonterminal in the intersection grammar matches a substring simultaneously recognized by (1) a pair of states in the original NFA and (2) a nonterminal in the original CFG. A key observation is that $\bowtie$ generates the Cartesian product of every such triple, but this is a gross overapproximation for most NFAs and CFGs, as the vast majority of all state pairs and nonterminals recognize no strings in common.

To identify these superfluous triples, we define an interval domain that soundly overapproximates the Parikh image, encoding the minimum and maximum number of terminals each nonterminal can generate. Since some intervals may be right-unbounded, we write $\mathbb{N}^* = \mathbb{N} \cup \{\infty\}$ to denote the upper bound, and $\Pi = \{[a,b] \in \mathbb{N} \times \mathbb{N}^* \mid a \le b\}^{|\Sigma|}$ to denote the Parikh image of all terminals.

Definition 4.2 (Parikh mapping of a nonterminal). Let $p : \Sigma^* \to \mathbb{N}^{|\Sigma|}$ be the Parikh operator [33], which counts the frequency of terminals in a string. We define the Parikh map, $\pi : V \to \Pi$, as a function returning the smallest interval such that $\forall \sigma : \Sigma^*, \forall v : V, v \Rightarrow^* \sigma \vdash p(\sigma) \in \pi(v)$.

In other words, the Parikh mapping computes the greatest lower and least upper bound of the Parikh image over all strings in the language of a nonterminal. The infimum of a nonterminal's Parikh interval tells us how many of each terminal a nonterminal *must* generate, and the supremum tells us how many it *can* generate. Likewise, we define a similar relation over NFA state pairs:

Definition 4.3 (Parikh mapping of NFA states). We define $\pi : Q \times Q \to \Pi$ as returning the smallest interval such that $\forall \sigma : \Sigma^*, \forall q, q' : Q, q \overset{\sigma}{\Longrightarrow} q' \vdash p(\sigma) \in \pi(q,q')$.

Next, we will define a measure on Parikh intervals representing the minimum total edits required to transform a string in one Parikh interval to a string in another, across all such pairings.

Definition 4.4 (Parikh divergence). Given two Parikh intervals $\pi, \pi' : \Pi$, we define the divergence between them as $\pi \parallel \pi' = \sum_{n=1}^{|\Sigma|} \min_{(i,i') \in \pi[n] \times \pi'[n]} |i - i'|$.

Now, we know that if the Parikh divergence between two intervals exceeds the Levenshtein margin between two states in a Lev-NFA, those intervals must be incompatible as no two strings, one from each Parikh interval, can be transformed into the other with fewer than $\pi \parallel \pi'$ edits.

Definition 4.5 (Levenshtein-Parikh compatibility). Let $q = q_{h,i}, q' = q_{j,k}$ be two states in a Lev-NFA and V be a CFG nonterminal. We say that $(q, v, q') : Q \times V \times Q$ are compatible iff the Parikh divergence is bounded by the Levenshtein margin $k - i$, i.e., $v \lhd qq' \iff (\pi(v) \parallel \pi(q,q')) \le k - i$.

Finally, we define the modified Bar-Hillel construction for nominal Levenshtein automata as:

$$\frac{(A \to a) \in P \quad S.a \quad (q \xrightarrow{S} r) \in \delta}{(qAr \to a) \in P_\cap} \qquad \frac{w \lhd pr \quad x \lhd pq \quad z \lhd qr \quad (w \to xz) \in P \quad p,q,r \in Q}{(pwr \to (pxq)(qzr)) \in P_\cap} \bowtie$$

After $G_\cap$ is constructed, we then renormalize it by removing all unreachable and non-generating productions following [20] to obtain $G'_\cap$, which is usually several orders of magnitude smaller.

Now that we have a language to recognize nearby repairs, we will need a method to generate the repairs themselves. We impose specific criteria on such a procedure: it must generate only valid repairs and all repairs in the language if possible, otherwise as many as can be sampled in an arbitrary but fixed timeout. In the following sections, we will describe a constructor (§ 4.4) for a data structure (§ 4.5) representing parse forests in a length-bounded CFL. Among other features, this data structure provides an explicit way to construct the Parikh map for the Levenshtein Bar-Hillel (LBH) construction, and a method for sampling the language with or without replacement.

4.4 Code completion as idempotent matrix completion

In this section, we will introduce the porous completion problem and show how it can be translated to a kind of idempotent matrix completion, whose roots are valid strings in a context-free language. This technique is convenient for its geometric interpretability, parallelizability, and generalizability to any CFG, regardless of finitude or ambiguity. We will see how, by redefining the algebraic operations $\oplus, \otimes$ over different carrier sets, one can obtain a recognizer, parser, generator, Parikh map and other convenient structures for working with CFLs.

Given a CFG, $G' : \mathcal{G}$ in Chomsky Normal Form (CNF), we can construct a recognizer $R : \mathcal{G} \to \Sigma^n \to \mathbb{B}$ for strings $\sigma : \Sigma^n$ as follows. Let 2^V be our domain, 0 be $\varnothing$, $\oplus$ be $\cup$, and $\otimes$ be defined as:

$$X \otimes Z = \left\{ w \mid \langle x, z \rangle \in X \times Z, (w \to xz) \in P \right\} \tag{2}$$

If we define $\hat{\sigma}_r = \{w \mid (w \to \sigma_r) \in P\}$, then construct a matrix with nonterminals on the superdiagonal representing each token, $M_0[r+1=c](G', \sigma) = \hat{\sigma}_r$, the fixpoint $M_{i+1} = M_i + M_i^2$ is uniquely determined by the superdiagonal entries, which are computed as follows:

$$M_0 = \begin{pmatrix} \varnothing & \hat{\sigma}_1 & \varnothing & \cdots & \varnothing \\ & \ddots & \ddots & \ddots & \vdots \\ & & \ddots & \ddots & \varnothing \\ & & & \ddots & \hat{\sigma}_n \\ \varnothing & & & & \varnothing \end{pmatrix} \Rightarrow \begin{pmatrix} \varnothing & \hat{\sigma}_1 & \Lambda & \cdots & \varnothing \\ & \ddots & \ddots & \ddots & \vdots \\ & & \ddots & \ddots & \Lambda \\ & & & \ddots & \hat{\sigma}_n \\ \varnothing & & & & \varnothing \end{pmatrix} \Rightarrow \ldots \Rightarrow M_\infty = \begin{pmatrix} \varnothing & \hat{\sigma}_1 & \Lambda & \cdots & \Lambda^*_\sigma \\ & \ddots & \ddots & \ddots & \vdots \\ & & \ddots & \ddots & \Lambda \\ & & & \ddots & \hat{\sigma}_n \\ \varnothing & & & & \varnothing \end{pmatrix}$$

Once obtained, the proposition $[S \in \Lambda^*_\sigma]$ decides language membership, i.e., $[\sigma \in \mathcal{L}(\mathcal{G})]$ [1]. So far, this procedure is essentially the textbook CYK algorithm in a linear algebraic notation [23].

This procedure can be lifted to the domain of strings containing free variables, which we call the *porous completion problem*. In this case, the fixpoint is characterized by a system of language equations, whose solutions are the set of all sentences consistent with the template.

Definition 4.6 (Porous completion). Let $\underline{\Sigma} = \Sigma \cup \{\_\}$, where _ denotes a hole. We denote $\sqsubseteq : \Sigma^n \times \underline{\Sigma}^n$ as the relation $\{\langle \sigma', \sigma \rangle \mid \sigma_i \in \Sigma \implies \sigma'_i = \sigma_i\}$ and the set of all inhabitants $\{\sigma' : \Sigma^+ \mid \sigma' \sqsubseteq \sigma\}$ as $\mathrm{H}(\sigma)$. Given a *porous string*, $\sigma : \underline{\Sigma}^*$ we seek all syntactically valid inhabitants, i.e., $A(\sigma) = \mathrm{H}(\sigma) \cap \ell$.

Let us consider an example with two holes, $\sigma = 1 \_ \_$, and the grammar being $G = \{S \to NON, O \to + \mid \times, N \to 0 \mid 1\}$. This can be rewritten into CNF as $G' = \{S \to NL, N \to 0 \mid 1, O \to \times \mid +, L \to ON\}$. Using the algebra where $\oplus = \cup$, $X \otimes Z = \left\{ w \mid \langle x, z \rangle \in X \times Z, (w \to xz) \in P \right\}$, the fixpoint $M' = M + M^2$ can be computed as follows, shown in the leftmost column:

[1] Hereinafter, we use Iverson brackets to denote the indicator function of a predicate with free variables, i.e., $[P] \Leftrightarrow \mathbb{1}(P)$.

	2^V	$\mathbb{Z}_2^{\lvert V\rvert}$	$\mathbb{Z}_2^{\lvert V\rvert} \to \mathbb{Z}_2^{\lvert V\rvert}$
M_0	$\begin{pmatrix} \{N\} & & \\ & \{N,O\} & \\ & & \{N,O\} \end{pmatrix}$	$\begin{pmatrix} \square\blacksquare\square\square & & \\ & \square\blacksquare\blacksquare\square & \\ & & \square\blacksquare\blacksquare\square \end{pmatrix}$	$\begin{pmatrix} V_{0,1} & & \\ & V_{1,2} & \\ & & V_{2,3} \end{pmatrix}$
M_1	$\begin{pmatrix} \{N\} & \varnothing & \\ & \{N,O\} & \{L\} \\ & & \{N,O\} \end{pmatrix}$	$\begin{pmatrix} \square\blacksquare\square\square & \square\square\square\square & \\ & \square\blacksquare\blacksquare\square & \blacksquare\square\square\square \\ & & \square\blacksquare\blacksquare\square \end{pmatrix}$	$\begin{pmatrix} V_{0,1} & V_{0,2} & \\ & V_{1,2} & V_{1,3} \\ & & V_{2,3} \end{pmatrix}$
$M_2 = M_\infty$	$\begin{pmatrix} \{N\} & \varnothing & \{S\} \\ & \{N,O\} & \{L\} \\ & & \{N,O\} \end{pmatrix}$	$\begin{pmatrix} \square\blacksquare\square\square & \square\square\square\square & \square\square\square\blacksquare \\ & \square\blacksquare\blacksquare\square & \blacksquare\square\square\square \\ & & \square\blacksquare\blacksquare\square \end{pmatrix}$	$\begin{pmatrix} V_{0,1} & V_{0,2} & V_{0,3} \\ & V_{1,2} & V_{1,3} \\ & & V_{2,3} \end{pmatrix}$

The same procedure can be translated, without loss of generality, into the bit domain ($\mathbb{Z}_2^{|V|}$) using a lexicographic ordering, however M_∞ in both 2^V and $\mathbb{Z}_2^{|V|}$ represents a decision procedure, i.e., $[S \in V_{0,3}] \Leftrightarrow [V_{0,3,3} = \blacksquare] \Leftrightarrow [A(\sigma) \neq \varnothing]$. Since $V_{0,3} = \{S\}$, we know there exists at least one $\sigma' \in A$, but M_∞ does not reveal its identity.

In order to extract the inhabitants, we can translate the bitwise procedure into an equation with free variables. Here, we can encode the idempotency constraint directly as $M = M^2$. We first define $X \boxtimes Z = [X_2 \wedge Z_1, \bot, \bot, X_1 \wedge Z_0]$ and $X \boxplus Z = [X_i \vee Z_i]_{i \in [0,|V|)}$. Since the unit nonterminals O, N can only occur on the superdiagonal, they may be safely ignored by $\boxtimes$. To solve for M_∞, we proceed by first computing $V_{0,2}, V_{1,3}$ as follows:

$$\begin{aligned} V_{0,2} &= V_{0,j} \cdot V_{j,2} = V_{0,1} \boxtimes V_{1,2} \\ &= [L \in V_{0,2}, \bot, \bot, S \in V_{0,2}] \\ &= [O \in V_{0,1} \wedge N \in V_{1,2}, \bot, \bot, N \in V_{0,1} \wedge L \in V_{1,2}] \\ &= [V_{0,1,2} \wedge V_{1,2,1}, \bot, \bot, V_{0,1,1} \wedge V_{1,2,0}] \end{aligned}$$

$$\begin{aligned} V_{1,3} &= V_{1,j} \cdot V_{j,3} = V_{1,2} \boxtimes V_{2,3} \\ &= [L \in V_{1,3}, \bot, \bot, S \in V_{1,3}] \\ &= [O \in V_{1,2} \wedge N \in V_{2,3}, \bot, \bot, N \in V_{1,2} \wedge L \in V_{2,3}] \\ &= [V_{1,2,2} \wedge V_{2,3,1}, \bot, \bot, V_{1,2,1} \wedge V_{2,3,0}] \end{aligned}$$

Now we solve for the corner entry $V_{0,3}$ by taking the bitwise dot product between the first row and last column, yielding:

$$\begin{aligned} V_{0,3} &= V_{0,j} \cdot V_{j,3} = V_{0,1} \boxtimes V_{1,3} \boxplus V_{0,2} \boxtimes V_{2,3} \\ &= [V_{0,1,2} \wedge V_{1,3,1} \vee V_{0,2,2} \wedge V_{2,3,1}, \bot, \bot, V_{0,1,1} \wedge V_{1,3,0} \vee V_{0,2,1} \wedge V_{2,3,0}] \end{aligned}$$

Since we only care about $V_{0,3,3} \Leftrightarrow [S \in V_{0,3}]$, so we can ignore the first three entries and solve for:

$$\begin{aligned} V_{0,3,3} &= V_{0,1,1} \wedge V_{1,3,0} \vee V_{0,2,1} \wedge V_{2,3,0} \\ &= V_{0,1,1} \wedge (V_{1,2,2} \wedge V_{2,3,1}) \vee V_{0,2,1} \wedge \bot \\ &= V_{0,1,1} \wedge V_{1,2,2} \wedge V_{2,3,1} \\ &= [N \in V_{0,1}] \wedge [O \in V_{1,2}] \wedge [N \in V_{2,3}] \end{aligned}$$

Now we know that $\sigma = 1\,\underline{O}\,\underline{N}$ is a valid solution, and we can take the product $\{1\} \times \hat{\sigma}_2^{-1}(O) \times \hat{\sigma}_3^{-1}(N)$ to recover the admissible set, yielding $A = \{1{+}0, 1{+}1, 1{\times}0, 1{\times}1\}$. In this case, since G is unambiguous, there is only one parse tree satisfying $V_{0,|\sigma|,3}$, but in general, there can be multiple valid parse trees.

4.5 An algebraic datatype for context-free parse forests

The procedure described in § 4.4 generates solutions satisfying the matrix fixpoint, but forgets provenance. The question naturally arises, is there a way to solve for the parse trees directly? This would allow us to handle ambiguous grammars, whilst preserving the natural treelike structure.

We will now describe a datatype for compactly representing CFL parse forests, then redefine the matrix algebra over this domain. This datatype is particularly convenient for tracking provenance under ambiguity, constructing the Parikh map for a CFG, counting the size of a finite CFL, and sampling parse trees with or without replacement.

We first define a datatype $\mathbb{T}_3 = (V \cup \Sigma) \rightharpoonup \mathbb{T}_2$ where $\mathbb{T}_2 = (V \cup \Sigma) \times (\mathbb{N} \rightharpoonup \mathbb{T}_2 \times \mathbb{T}_2)$[2]. Morally, we can think of $\mathbb{T}_2$ as an implicit set of possible trees that can be generated by a CFG in CNF, consistent with a finite-length porous string. Structurally, we may interpret $\mathbb{T}_2$ as an algebraic data type corresponding to the fixpoints of the following recurrence, which tells us each $\mathbb{T}_2$ can be a terminal, nonterminal, or a nonterminal and a sequence of nonterminal pairs and their two children:

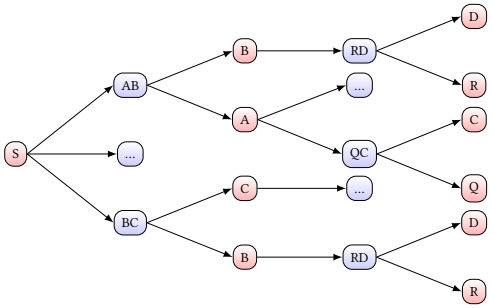


Fig. 3. A partial $\mathbb{T}_2$ corresponding to the grammar $\{S \to BC \mid \ldots \mid AB, B \to RD \mid \ldots, A \to QC \mid \ldots\}$.

$$L(p) = 1 + pL(p) \qquad P(a) = \Sigma + V + VL\left(V^2 P(a)^2\right) \tag{3}$$

Depicted in Fig. 3 is a partial $\mathbb{T}_2$, where red nodes are `roots` and blue nodes are `children`. The shape of type $\mathbb{T}_2$ is congruent with an acyclic CFG in Chomsky Normal Form, i.e., $\mathbb{T}_2 \cong \mathcal{G}'$, so assuming the CFG recognizes a finite language, as the case for $G'_\cap$, we can translate it directly. If the language is infinite, we slice the CFL, $\mathcal{L}(G) \cap \Sigma^n$, and compute the fixpoint for each slice.

Given a porous string $\sigma : \underline{\Sigma}^n$ representing the slice, we can construct $\mathbb{T}_2$ from the bottom-up, and read off structures from the top-down. We construct the first upper diagonal $\hat{\sigma}_r = \Lambda(\sigma_r)$ as follows:

$$\Lambda(s : \underline{\Sigma}^n) \mapsto \begin{cases} \bigoplus_{s' \in \Sigma} \Lambda(s') & \text{if } s \text{ is a hole,} \\ \left\{ \mathbb{T}_2\left(w, \left[\langle \mathbb{T}_2(s), \mathbb{T}_2(\varepsilon) \rangle\right]\right) \mid (w \to s) \in P \right\} & \text{otherwise.} \end{cases} \tag{4}$$

This initializes the superdiagonal entries of M_0, enabling us to compute the fixpoint M_∞ in the same manner described in § 4.4 by redefining $\oplus, \otimes : \mathbb{T}_3 \times \mathbb{T}_3 \to \mathbb{T}_3$ as:

$$X \oplus Z \mapsto \bigcup_{k \in \pi_1(X \cup Z)} \left\{ k \Rightarrow \mathbb{T}_2(k, x \cup z) \mid x \in \pi_2(X \circ k), z \in \pi_2(Z \circ k) \right\} \tag{5}$$

$$X \otimes Z \mapsto \bigoplus_{(w \to xz) \in P} \left\{ \mathbb{T}_2\Big(w, \left[\langle X \circ x, Z \circ z \rangle\right]\Big) \mid x \in \pi_1(X), z \in \pi_1(Z) \right\} \tag{6}$$

These operators group subtrees by their root nonterminal, then aggregate their children. Instead of tracking sets, each Λ now becomes a dictionary of $\mathbb{T}_2$, indexed by their root nonterminals.

$\mathbb{T}_2$ is a convenient datatype for many operations involving CFGs. We can use it to approximate the Parikh image, compute the size of a finite CFG, and sample parse trees with or without replacement. For example, to obtain the Parikh map of a CFG (Def. 4.2), we may use the following recurrence,

$$\pi(T : \mathbb{T}_2) \mapsto \begin{cases} \left[[1,1] \text{ if } \texttt{root}(T) = s \text{ else } [0,0] \right]_{s \in \Sigma} & \text{if } T \text{ is a leaf,} \\ \bigoplus_{\langle T_1, T_2 \rangle \in \texttt{children}(T)} \pi(T_1) \otimes \pi(T_2) & \text{otherwise.} \end{cases} \tag{7}$$

[2]Given a $T : \mathbb{T}_2$, we may also refer to $\pi_1(T), \pi_2(T)$ as $\texttt{root}(T)$ and $\texttt{children}(T)$ respectively.

where the operations over Parikh maps $\oplus, \otimes : \Pi \times \Pi \to \Pi$ are defined respectively as follows:

$$X \oplus Z \mapsto \left[\left[\min(X_s \cup Z_s), \max(X_s \cup Z_s)\right]\right]_{s \in \Sigma} \tag{8}$$

$$X \otimes Z \mapsto \left[\left[\min(X_s) + \min(Z_s), \max(X_s) + \max(Z_s)\right]\right]_{s \in \Sigma} \tag{9}$$

To obtain the parameterized Parikh map of a length-bounded CFG, we abstractly parse the porous string and take the union of all intervals, which subsumes every repair in the Levenshtein ball. Given a specific programming language syntax, G, the following function can be precomputed and cached for all $v : V$, and small values of $n, d : \mathbb{N}$ for the sake of efficiency, then used to retrieve the Levenshtein-Parikh-$\langle v, n, d\rangle$ map for any invalid string $\underset{\sim}{\sigma}$ of length n in constant time:

$$\pi(G : \mathcal{G}, v : V, n : \mathbb{N}, d : \mathbb{N}) : \Pi = \bigoplus_{i \in [n-d, n+d]} \pi\left(\Lambda^*(\{\_\}^i) \circ v\right) \tag{10}$$

$\mathbb{T}_2$ also allows us to sample whole parse trees by constructing $(\Lambda^*(\sigma) \circ S) : \mathbb{T}_2$ from the bottom-up and sampling top-down. Given a PCFG whose productions indexed by each nonterminal are decorated with a probability vector $\mathbf{p}$ (uniform in the non-probabilistic case), we define a tree sampler $\Gamma : (\mathbb{T}_2 \mid \mathbb{T}_2^2) \rightsquigarrow \mathbb{T}$ which recursively draws children according to a Multinoulli distribution:

$$\Gamma(T) \mapsto \begin{cases} \texttt{BTree}\Big(\texttt{root}(T), \Gamma\big(\text{Multi}(\texttt{children}(T), \mathbf{p})\big)\Big) & \text{if } T : \mathbb{T}_2 \\ \Big\langle \Gamma\big(\pi_1(T)\big), \Gamma\big(\pi_2(T)\big)\Big\rangle & \text{if } T : \mathbb{T}_2 \times \mathbb{T}_2 \end{cases} \tag{11}$$

This method is closely related to the generating function for the ordinary Boltzmann sampler,

$$\Gamma C(x) \mapsto \begin{cases} \text{Bern}\left(\frac{A(x)}{A(x)+B(x)}\right) \to \Gamma A(x) \mid \Gamma B(x) & \text{if } \mathcal{C} = \mathcal{A} + \mathcal{B} \\ \big\langle \Gamma A(x), \Gamma B(x)\big\rangle & \text{if } \mathcal{C} = \mathcal{A} \times \mathcal{B} \end{cases} \tag{12}$$

from analytic combinatorics, however unlike Duchon et al. [18], our work does not depend on rejection to guarantee exact-size sampling, as all trees from $\mathbb{T}_2$ will necessarily be the same width.

The number of binary trees inhabiting a single instance of $\mathbb{T}_2$ is sensitive to the number of nonterminals and rule expansions in the grammar. To obtain the total number of trees with breadth n, we abstractly parse the porous string, letting $T = \Lambda^*(\{\_\}^n) \circ S$, then use the recurrence below to compute the total number of unique trees in the language:

$$|T : \mathbb{T}_2| \mapsto \begin{cases} 1 & \text{if } T \text{ is a leaf,} \\ \sum_{\langle T_1, T_2\rangle \in \texttt{children}(T)} |T_1| \cdot |T_2| & \text{otherwise.} \end{cases} \tag{13}$$

To sample all trees in a given $T : \mathbb{T}_2$ uniformly without replacement, we then construct a modular pairing function $\varphi : \mathbb{T}_2 \to \mathbb{Z}_{|T|} \to \texttt{BTree}$, that we define as follows:

$$\varphi(T : \mathbb{T}_2, i : \mathbb{Z}_{|T|}) \mapsto \begin{cases} \Big\langle \texttt{BTree}\big(\texttt{root}(T)\big), i\Big\rangle & \text{if } T \text{ is a leaf,} \\ \text{Let } b = |\texttt{children}(T)|, & \\ \quad q_1, r = \left\langle \lfloor \frac{i}{b} \rfloor, i \pmod b \right\rangle, & \\ \quad lb, rb = \texttt{children}[r], & \\ \quad T_1, q_2 = \varphi(lb, q_1), & \\ \quad T_2, q_3 = \varphi(rb, q_2) \text{ in} & \\ \Big\langle \texttt{BTree}\big(\texttt{root}(T), T_1, T_2\big), q_3\Big\rangle & \text{otherwise.} \end{cases} \tag{14}$$

Then, instead of top-down incremental sampling, we can sample integers uniformly without replacement from $\mathbb{Z}_{|T|}$ then decode them into whole parse trees using φ. If the language is sufficiently small, we can enumerate every tree, otherwise, we sample them uniformly without replacement, or with replacement using a PCFG. This procedure is the basis for our enumerate sampler and the method we use to decode repairs from the intersection grammar.

4.6 Ranked repair

Returning to the ranked repair problem (Def. 3.2), the above procedure returns a set of consistent repairs, and we need an ordering over them. We note that any metric is sufficient, such as the log likelihood of the repair under a large language model or the probability under a PCFG and turn to simplest solution: the likelihood of a low-order Markov chain. This solution is computationally fast, and as we will show, yields competitive results in practice.

Specifically, given a string $\sigma : \Sigma^*$, we factorize the probability $P_\theta(\sigma)$ as a product of conditionals $\prod_{i=1}^{|\sigma|} P_\theta(\sigma_i \mid \sigma_{i-1} \dots \sigma_{i-n})$, for some small $n \in \mathbb{N}$. To obtain the parameters θ, we use the standard maximum likelihood estimator for Markov chains. We approximate the joint distribution $P(\Sigma^n)$ directly from data, then the conditionals by normalizing n-gram counts with Laplace smoothing.

To score the repairs, we use the conventional length-normalized negative log likelihood:

$$\mathrm{NLL}(\sigma) = -\frac{1}{|\sigma|} \sum_{i=1}^{|\sigma|} \log P_\theta(\sigma_i \mid \sigma_{i-1} \dots \sigma_{i-n}) \tag{15}$$

Then, for each $\sigma \in A(\underline{\sigma})$, we score the repair and return the admissible set in ascending order. That is, we impose an ordering over $A(\underline{\sigma})$, where the first repair is most likely under the model, and the last is least likely. To evaluate the accuracy of our ranking, we use the Precision@k statistic, which measures the frequency of repairs in the top-k results matching the true repair. Specifically, given a repair model, $R : \Sigma^* \to 2^{\Sigma^*}$ and a test set $\mathcal{D}_{\text{test}}$, we define Precision@k as:

$$\mathrm{Precision@k}(R) = \frac{1}{|\mathcal{D}_{\text{test}}|} \sum_{\langle \sigma^\dagger, \sigma' \rangle \in \mathcal{D}_{\text{test}}} \mathbb{1}\left[\sigma' \in \operatorname*{argmax}_{\boldsymbol{\sigma} \subset R(\sigma^\dagger), |\boldsymbol{\sigma}| \le k} \sum_{\sigma \in \boldsymbol{\sigma}} \mathrm{NLL}(\sigma)\right] \tag{16}$$

This is a variation on a standard metric used in information retrieval, and a common way to measure the quality of ranked results in machine translation and recommender systems.

5 EXPERIMENTAL SETUP

We use syntax errors and fixes from the Python language to validate our approach. Python source code fragments are abstracted as a sequence of lexical tokens using the official Python lexer, erasing numbers and identifiers, but retaining all other keywords. Precision is evaluated across a test set by checking for lexical equivalence with the ground-truth repair, following Sakkas et al. (2022) [36].

We compare our method against two separate baselines, Seq2Parse and Break-It-Fix-It (BIFI) [41] on a single test set. This dataset [40] consists of 20k naturally-occurring pairs of Python errors and their corresponding human fixes from StackOverflow and is used compare the precision of each method at blind recovery of the ground truth repair across varying edit distances, snippet lengths and latency cutoffs. We preprocess all source code by filtering for broken-fixed snippet pairs shorter than 80 tokens and fewer than five Levenshtein edits apart, whose broken and fixed form is accepted and rejected, respectively, by the Python 3.8.11 parser. We then balance the dataset by sampling an equal number of repairs from each length and Levenshtein edit distance.

The Seq2Parse and BIFI experiments were conducted on a single Nvidia V100 GPU with 32 GB of RAM. For Seq2Parse, we use the default pretrained model provided in commit `7ae0681` [3]. Since it was unclear how to extract multiple repairs from their model, we only take a single repair prediction. For BIFI, we use the Round 2 breaker and fixer from commit `ee2a68c`[4], the highest-performing model reported by the authors, with a variable-width beam search to control the number of predictions, and let the fixer model predict the top-k repairs, for $k = \{1, 5, 10, 20 \times 10^5\}$.

The language intersection experiments were conducted on 40 Intel Skylake cores running at 2.4 GHz, with 150 GB of RAM, running bytecode compiled for JVM 17.0.2. To train our scoring function, we use a order-5 Markov chain trained on 55 million BIFI tokens. Training takes roughly 10 minutes, after which re-ranking is nearly instantaneous. Sequences are scored using NLL with Laplace smoothing and our evaluation measures the Precision@{1, 5, 10, All} for samples at varying latency cutoffs. We apply a 30-second latency cutoff for our sampler.

6 EVALUATION

We call our method Tidyparse and consider the following research questions:

- **RQ 1**: What statistical properties do natural repairs exhibit? (e.g., length, edit distance)
- **RQ 2**: How performant is Tidyparse at fixing syntax errors? (i.e., vs. Seq2Parse and BIFI)
- **RQ 3**: Which design choices are most significant? (e.g., search vs. sampling, parallelism)

We address **RQ 1** in § 6.1 by analyzing the distribution of natural Python repair lengths and distances, **RQ 2** in § 6.2 by comparing Tidyparse against two existing syntax repair baselines, and **RQ 3** in § 6.3 by ablating various design choices and evaluating the impact on repair precision.

6.1 Dataset

In the following experiments, we use a dataset of Python snippets consisting of 20,500 pairwise-aligned human errors and fixes from StackOverflow [40]. We preprocess the dataset to lexicalize all code snippets, then filter by length and distance shorter than 80 lexical tokens and under five edits, i.e., where pairwise Levenshtein distance is under five lexical edits ($|\Sigma| = 50, |\underset{\sim}{\sigma}| < 80, \Delta(\underset{\sim}{\sigma}, \sigma') < 5$). We depict the length, edit distance, normalized edit locations and stability profile in Fig. 4.

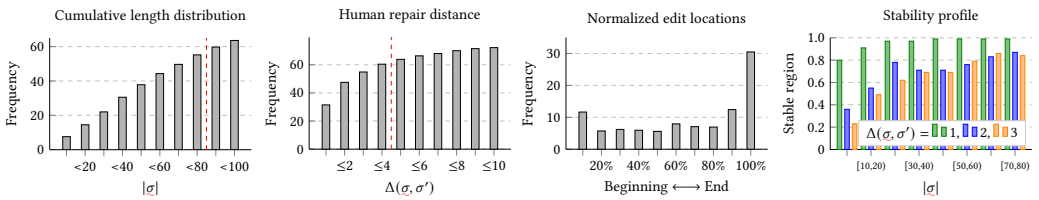

Fig. 4. Repair statistics across the StackOverflow dataset, of which Tidyparse can handle about half in under ~30s and ~150 GB. Larger repairs and edit distances are possible, albeit requiring additional time and memory.

For the stability profile, we enumerate repairs for each syntax error and estimate the average fraction of all edit locations that were never altered by any repair in the $L(\underset{\sim}{\sigma}, \Delta(\underset{\sim}{\sigma}, \sigma'))$-ball. For example, on average roughly half of the string is stable for 3-edit syntax repairs in the $[10 - 20)$ token range, whereas 1-edit repairs of the same length could modify only $\sim$ 10% of all locations. For a fixed edit distance, we observe an overall decrease in the number of degrees of caret freedom with increasing length, which intuitively makes sense, as the repairs are more heavily constrained by the surrounding context and their locations grow more concentrated relative to the entire string.

6.2 StackOverflow evaluation

For our first experiment, we measure the precision of our repair procedure at various lengths and Levenshtein distances. We rebalance the StackOverflow dataset across each length interval and edit distance, sample uniformly from each category and compare Precision@1 of our method against Seq2Parse, vanilla BIFI and BIFI with a beam size and precision at 20k distinct samples.

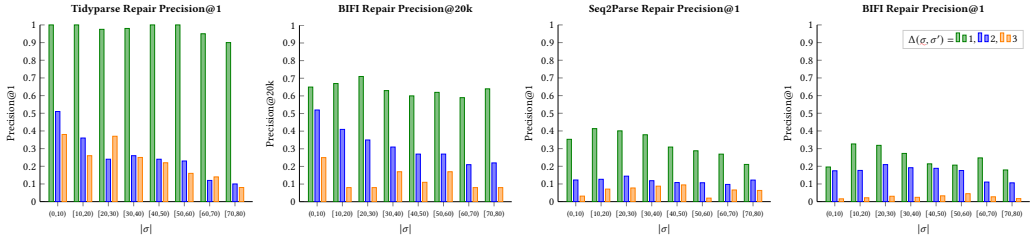

Fig. 5. Tidyparse, Seq2Parse and BIFI repair precision at various lengths and Levenshtein distances.

As we can see, Tidyparse has a highly competitive top-1 precision versus Seq2Parse and BIFI across all lengths and edit distances, and attains a significant advantage in the few-edit regime. The Precision@1 of our method is even competitive with BIFI's Precision@20k, whereas our Precision@All is Pareto-dominant across all lengths and edit distances, while requiring only a fraction of the data and compute. We report the raw data from these experiments in Appendix B.

Next, we measure the precision at various ranking cutoffs and wall-clock timeouts. Our method attains the same precision as Seq2Parse and BIFI for 1-edit repairs at comparable latency, however Tidyparse takes longer to attain the same precision for 2- and 3-edit repairs. BIFI and Seq2Parse both have subsecond single-shot latency but are neural models trained on a much larger dataset.

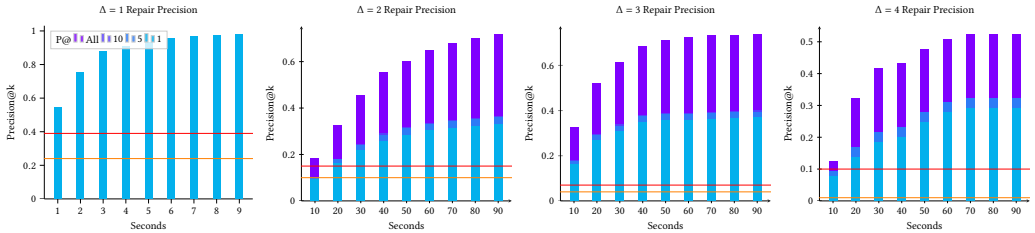

Fig. 6. Human repair benchmarks. Note the y-axis across different edit distance plots has varying ranges. The red line indicates Seq2Parse and the orange line indicates BIFI's Precision@1 on the same repairs.

We present a Sankey diagram of our repair pipeline in Fig. 7. We drew 967 total repairs from the StackOverflow dataset balanced evenly across lengths and edit distances ($\lfloor |\underset{\sim}{\sigma}|/10 \rfloor \in [0, 8], \Delta(\underset{\sim}{\sigma}, \sigma') < 4$) with a timeout of 30s and tracked individual outcomes. In 87 cases, the intersection grammar was too large to construct and threw an out-of-memory (OOM) error, in 4 cases the human repair was not recognized, in 153 cases the sampler timed out before drawing the human repair, in 238 cases the human repair was drawn but not ranked first, and in the remaining 485 cases the first prediction matched the human repair.

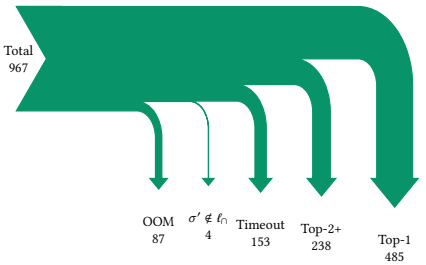

Fig. 7. Outcomes in the repair pipeline.

The remaining experiments in this section were run on a 10-core ARM64 M1 with 16 GB of memory. We balance the StackOverflow dataset across Levenshtein distances, then measure the number of samples required to draw the exact human repair across varying Levenshtein radii. This tells us of how many samples are required on average to saturate the admissible set.

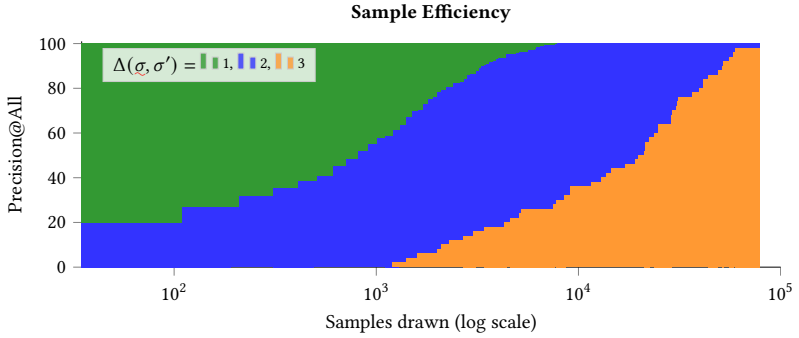

Fig. 8. Sample efficiency of Tidyparse at varying Levenshtein radii. After drawing up to $\sim 10^5$ samples without replacement we can usually retrieve the human repair for almost all repairs fewer than four edits.

End-to-end throughput varies significantly with the edit distance of the repair. Some errors are trivial to fix, while others require a large number of edits to be sampled before the ground truth is discovered. We evaluate throughput by sampling edits across invalid strings $|\sigma| \leq 40$ from the StackOverflow dataset balanced across length and distance, and measure the total number of syntactically valid edits discovered, as a function of string length and edit distance $\Delta \in [1, 4]$. Each trial is terminated after 10 seconds, and the experiment is repeated across 7.3k total repairs. Note the y-axis is log-scaled, as the number of admissible repairs increases sharply with edit distance. Our approach discovers a large number of syntactic repairs in a relatively short amount of time, and is able to quickly saturate the admissible set for $\Delta(\sigma, \sigma') \in [1, 4]$ before timeout.

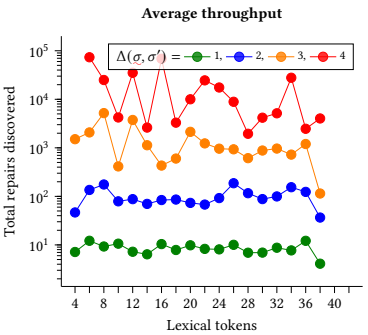

Fig. 9. Distinct repairs found in 30s.

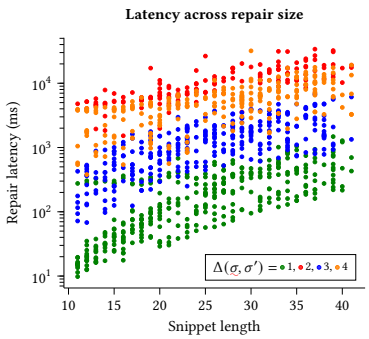

Fig. 10. End-to-end repair timings.

In Fig. 10, we plot the end-to-end repair timings by collecting 1000 samples balanced across length and edit distance, then measure the wallclock time until the sampler retrieves the human repair and report the log latency. While short repairs finish quickly, latency is positively correlated with length and edit distance. Our method is typically able to saturate the admissible set for 1- and 2-edit repairs before timeout, while 4+-edit throughput starts becoming constrained by compute around 30s, when Python's admissible set approaches a volume of 10^5 valid edits. This bottleneck can be relaxed with a longer timeout or additional CPU cores. We anticipate that a much longer delay will begin to tax the patience of most users, and so we consider 30s a reasonable upper bound for repair latency. As we will now show, end-to-end latency can be improved by doing rejection sampling, albeit at the cost of naturalness and sample efficiency.

6.3 Subcomponent ablation

Originally, we used a rejection-based sampler, which did not sample directly from the admissible set, but the entire Levenshtein ball, and then rejected invalid samples. Although rejection sampling has a much lower minimum latency threshold to return admissible repairs, i.e., a few seconds at most, the average time required to attain a desired precision on human repairs is much higher. We present the results from the rejection-based evaluation for comparison below.

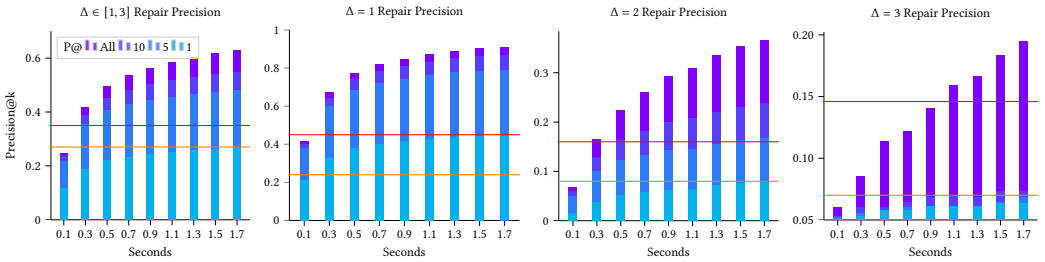

Fig. 11. Adaptive sampling repairs. The red line indicates Seq2Parse Precision@1 on the same dataset, and the orange indicates BIFI's precision at single-shot repair.

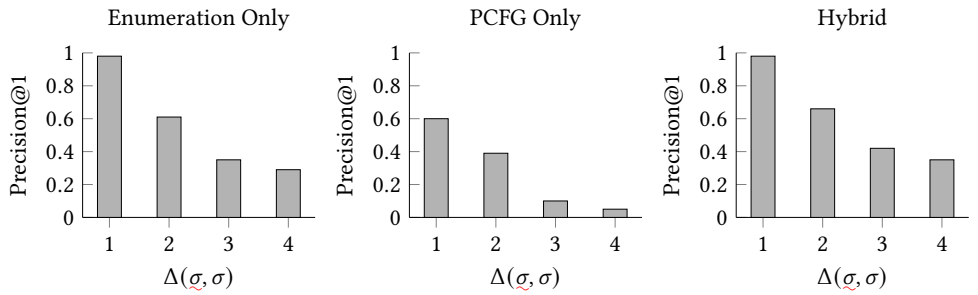
We also evaluate Seq2Parse on the same dataset. Seq2Parse only supports Precision@1 repairs, and so we only report Seq2parse Precision@1 from the StackOverflow benchmark for comparison. Unlike our approach which only produces syntactically correct repairs, Seq2Parse and BIFI also produce syntactically incorrect repairs in practice. The overall latency of Seq2Parse varies depending on the length of the repair, averaging 1.5s for $\Delta = 1$ to 2.7s for $\Delta = 3$, across the entire StackOverflow dataset, while BIFI consistently achieves subsecond latency across all repairs and distances.

Next, we conduct an ablation study to compare the effectiveness of PCFG sampling vs. enumeration. In both experiments, we balance the StackOverflow dataset across edit distances and run the repair extractor for up to 30 seconds (either enumerative or PCFG), then rerank all repairs by n-gram perplexity and measure the Precision@1 for sampling, enumeration, and the hybrid approach, which uses enumeration if the intersection grammar size $|G_\cap|$ is less than 10,000, and PCFG sampling otherwise.



While the overall precision is notably lower for PCFG sampling than enumeration, the average number of samples drawn is also significantly lower, indicating a relatively higher sample efficiency. This illustrates the tradeoff between sample efficiency and diversity, and suggests that a hybrid approach may be the most effective. When the repair language is very large, a PCFG offers a more informed prior, albeit at the cost of lower coverage.

In general, enumeration has an advantage when the CFL is small. For example, if the CFL contains 2,000 sentences, enumeration will recover all 2,000, whereas PCFG sampling may only recover 100 of the most likely samples. However, if the CFL has 200,000 sentences, enumeration may only be able to recover 10,000 uniform random samples and the PCFG may only recover 5,000, but due to the higher sample efficiency, the PCFG samples are more likely to contain the human repair.

We also measure the relative improvement in throughput (measured by the number of distinct repairs found after 30s) as a function of the number of additional CPU cores, averaged across 1000 trials. We observe from Fig.12 the relative throughput increases logarithmically with the number of additional CPU cores, with at least four CPU cores needed to offset the parallelization overhead. Generally, increasing parallelism only helps when the size of the admissible set is large enough to absorb the additional computation, which is seldom the case for small-radii Levenshtein balls. Further speedups may be possible to realize by rewriting the sampler in CUDA, which we leave for future work.

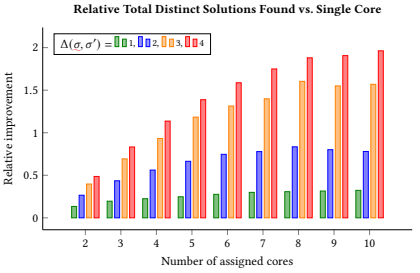


Fig. 12. Observed improvement in throughput relative to total CPU cores assigned.

7 DISCUSSION

The main lesson we draw from our experiments is that it is possible to leverage compute to compete with large language models on practical program repair tasks. Though sample-efficient, their size comes at the cost of expensive training, and domain adaptation requires fine-tuning or retraining on pairwise repairs. Our approach uses a small grammar and a relatively cheap ranking metric to achieve significantly higher precision. This allows us to repair errors in languages with little to no training data and provides far more flexibility and controllability.

Our primary insight leading to state-of-the-art precision is that repairs are typically concentrated near the center of a small Levenshtein ball, and by enumerating or sampling it carefully, then reranking all repairs found we can achieve a significant improvement over one-shot neural repair. We note this approach may not succeed in all languages, and it may be possible to construct pathological cases where the metastability heuristic fails.

Latency can vary depending on many factors including string length and grammar size, and critically the Levenshtein edit distance. This can be an advantage because in the absence of any contextual or statistical information, syntax and Levenshtein edits are often sufficiently constrained to identify a small number of valid repairs. It is also a limitation because as the number of edits grows, the admissible set grows rapidly and the number of valid repairs may become too large to be useful without a good metric, depending on the language and source code snippet under repair.

Tidyparse in its current form has several other technical shortcomings: firstly, it does not incorporate any neural language modeling technology at present, an omission we hope to address. Training a language model to predict likely repair locations and rank admissible results could lead to lower overall latency and more natural repairs. We also hope to explore the use of sequential Monte-Carlo [29] to encourage constrained sampling with diversity.

Lastly and perhaps most significantly, Tidyparse does not incorporate any semantic constraints, so its repairs whilst syntactically admissible, are not guaranteed to be semantically valid. This can be partly alleviated by filtering the results through an incremental compiler or linter, however, the latency introduced may be non-negligible. It is also possible to encode type-based semantic constraints into the solver and we intend to explore this direction more fully in future work.

We envision a few primary use cases for our tool: (1) helping novice programmers become more quickly familiar with a new programming language, (2) autocorrecting common typos among proficient but forgetful programmers, (3) as a prototyping tool for PL designers and educators, and (4) as a pluggable library or service for parser-generators and language servers. Featuring a grammar editor and built-in syntax repair, Tidyparse helps developers navigate the language design space, visualize syntax trees, debug parsing errors and quickly generate simple examples and counterexamples for benchmarking and testing.

8 RELATED WORK

Three important questions arise when repairing syntax errors: (1) is the program broken in the first place? (2) if so, where are the errors located? (3) how should those locations then be altered? In the case of syntax correction, those questions are addressed by three related research areas, (1) parsing, (2) language equations and (3) repair. We survey each of those areas in turn.

8.1 Parsing

Context-free language (CFL) parsing is the well-studied problem of how to turn a string into a unique tree, with many different algorithms and implementations (e.g., shift-reduce, recursive-descent, LR). Many of those algorithms expect grammars to be expressed in a certain form (e.g., left- or right- recursive) or are optimized for a narrow class of grammars (e.g., regular, linear).

General CFL parsing allows ambiguity (non-unique trees) and can be formulated as a dynamic programming problem, as shown by Cocke-Younger-Kasami (CYK) [35], Earley [19] and others. These parsers have roughly cubic complexity with respect to the length of the input string.

As shown by Valiant [39], Lee [27] and others, general CFL recognition is in some sense equivalent to binary matrix multiplication, another well-studied combinatorial problem with broad applications, known to be at worst subcubic. This reduction opens the door to a range of complexity-theoretic speedups to CFL recognition, however large constants tend to limit their practical utility.

8.2 Language equations

Language equations are a powerful tool for reasoning about formal languages and their inhabitants. First proposed by Ginsburg et al. [22] for the ALGOL language, language equations are essentially systems of inequalities with variables representing *holes*, i.e., unknown values, in the language or grammar. Solutions to these equations can be obtained using various fixpoint techniques, yielding members of the language. This insight reveals the true algebraic nature of CFLs and their cousins.

Being an algebraic formalism, language equations naturally give rise to a kind of calculus, vaguely reminiscent of Leibniz' and Newton's. First studied by Brzozowski [11, 12] and Antimirov [4], one can take the derivative of a language equation, yielding another equation. This can be interpreted as a kind of continuation or language quotient, revealing the suffixes that complete a given prefix. This technique leads to an elegant family of algorithms for incremental parsing [1, 31] and automata minimization [10]. In our setting, differentiation corresponds to code completion.

Bar-Hillel [5] establishes the closure of CFLs under intersection with regular languages, but does not elaborate on how to construct the corresponding grammar in order to recognize it. Beigel [8] and Pasti et al. [34] provide helpful insights into the construction of the intersection grammar, which our work specializes to intersection with nominal Levenshtein automata.

In this paper, we restrict our attention to language equations for context-free languages, whose variables coincide with edit locations in the source code of a computer program, and solutions correspond to syntax repairs. Although prior work has studied the use of language equations for parsing [31], to our knowledge they have never specifically been considered for the purpose of code completion or syntax error correction.

8.3 Syntax repair

In finite languages, syntax repair corresponds to spelling correction, a more restrictive and largely solved problem. Schulz and Stoyan [37] construct a finite automaton that returns the nearest dictionary entry by Levenshtein edit distance. Though considerably simpler than syntax correction, their work shares similar challenges and offers insights for handling more general repair scenarios.

When a sentence is grammatically invalid, parsing grows more challenging. Like spelling, the problem is to find the minimum number of edits required to transform an arbitrary string into a syntactically valid one, where validity is defined as containment in a (typically) context-free language. Early work, including Irons [25] and Aho [2] propose a dynamic programming algorithm to compute the minimum number of edits required to fix an invalid string. Prior work on error correcting parsing only considers the shortest edit(s), and does not study multiple edits over the Levenshtein ball. Furthermore, the problem of actually generating the repairs is not well-posed, as there are usually many valid strings that can be obtained within a given number of edits. We instead focus on bounded Levenshtein reachability, which is the problem of finding useful repairs within a fixed Levenshtein distance of the broken string, which requires language intersection.

8.4 String constraint solving

There is related work on string constraints in the constraint programing literature, featuring solvers like CFGAnalyzer and HAMPI [26], which consider bounded context free grammars and intersections thereof. Bojańczyk et al. (2014) [9] introduce the theory of nominal automata. Around the same time, D'Antoni et al. (2014) introduce *symbolic automata* [15], a generalization of finite automata which allow infinite alphabets and symbolic expressions over them. Hague et al. (2024) [24] use Parikh's theorem in the context of symbolic automata to speed up string constraint solving, from which we draw partial inspiration for the Levenshtein-Bar-Hillel construction in § 4.3. In none of the constraint programming literature we surveyed do any of the approaches specifically consider the problem of syntax error correction, which is the main focus of our work.

8.5 Error correcting codes

Our work focuses on errors arising from human factors in computer programming, in particular *syntax error correction*, which is the problem of fixing partially corrupted programs. Modern research on error correction, however, can be traced back to the early days of coding theory when researchers designed *error-correcting codes* (ECCs) to denoise transmission errors induced by external interference, e.g., collision with a high-energy proton, manipulation by an adversary or even typographical mistake. In this context, *code* can be any logical representation for communicating information between two parties (such as a human and a computer), and an ECC is a carefully-designed scheme which ensures that even if some portion of the message should become corrupted, one can still recover the original message by solving a linear system of equations. When designing ECCs, one typically assumes a noise model over a certain sample space, such as the Hamming [16, 38] or Levenshtein [6, 7, 28] balls, from which we draw inspiration for this work.

8.6 Neural program repair

The recent success of deep learning has lead to a variety of work on neural program repair [3, 14, 17]. These approaches typically employ Transformer-based large language models (LLMs) and model the problem as a sequence-to-sequence transformation. Although recent work on circuit lower bounds have cast doubt on the ability of Transformers to truly learn formal languages [13, 30], expressivity aside, these models have been widely adopted for practical program repair tasks. In particular, two papers stand out being closely related to our own: Break-It-Fix-It (BIFI) [41] and Seq2Parse [36].

BIFI adapts techniques from semi-supervised learning to generate synthetic errors in clean code and fixes them. This reduces the amount of pairwise training data, but tends to generalize poorly to length and out-of-distribution repairs. Seq2Parse combines a transformer-based model with an augmented version of the Early parser to suggest error rules, but only suggests a single repair. Our work differs from both in that we suggest multiple repairs at much higher precision, do not require a pairwise repair dataset, and can fix syntax errors in any language with a well-defined grammar. We note our approach is complementary to existing work in neural program repair, and may be used to generate synthetic repairs for training or employ an LLM for ranking.

9 CONCLUSION

Our work, while a case study on syntax repair, is part of a broader line of inquiry in program synthesis that investigates how to combine the strengths of formal language theory and machine learning to build more powerful and flexible programming tools. One approach is to filter the outputs of a generative language model to satisfy a formal specification, typically by constrained sampling. Alternatively, some attempt to use a formal language to guide the search for valid programs via a reinforcement learning or hybrid neurosymbolic approach.

In our work, we take a more pragmatic tack - by incorporating the distance metric into a formal language, we try to exhaustively enumerate repairs by increasing distance, then use the stochastic language model to rank the resulting solutions by naturalness. The more constraints we can encode into the formal language, the more efficient sampling becomes, and the more precise control we have over the output. This reduces the need for training a large, expensive language model to relearn syntax, and allows us to leverage compute for more efficient search.

The great compromise in program synthesis is one of efficiency versus expressiveness. The more expressive a language, the more concise and varied the programs it can represent, but the harder those programs are to synthesize without resorting to domain-specific heuristics. Likewise, the simpler a language is to synthesize, the weaker its concision and expressive power.

Most existing work on program synthesis has focused on general λ-calculi, or narrow languages such as finite sets or regular expressions. The former are too expressive to be efficiently synthesized or verified, whilst the latter are too restrictive to be useful. In our work, we focus on context-free and mildly context-sensitive grammars, which are expressive enough to capture a variety of useful programming language features, but not so expressive as to be unsynthesizable.

The second great tradeoff in program synthesis is that of soundness versus completeness. Most research in program synthesis improves one at the expense of the other, because they target a language that is too expressive to achieve both. In syntax repair, we also care about *naturalness*. Fortunately, syntax repair is tractable enough to achieve all three. We show that by modeling repair as a language intersection problem, we can achieve both soundness and completeness, and generate repairs that are always correct, and likely to be written by a human. Completeness helps us to avoid missing valid repairs, and also improves the naturalness of generated repairs.

Over the last few years, there has been a surge of progress in applying language models to write programs. That work is primarily based on methods from differential calculus and continuous optimization, leading to the so-called *naturalness hypothesis*, which suggests programming languages are not so different from natural ones. In contrast, programming language theory takes the view that languages are essentially discrete and finitely-generated sets governed by logical calculi. Programming, thus viewed, is more like a mathematical exercise in constraint satisfaction. These constraints naturally arise at various stages of syntax validation, type-checking and runtime verification, and help to ensure programs fulfill their intended purpose.

As our work shows, not only is linear algebra over finite fields an expressive language for probabilistic inference, but also an efficient framework for inference on languages themselves.

Borrowing analysis techniques from multilinear algebra and tensor completion in the machine learning setting, we develop an equational theory that allows us to translate various decision problems on formal languages into a system of inequalities over finite fields. We demonstrate the effectiveness of our approach for syntax repair in context-free languages, and show that our approach is competitive with state-of-the-art methods in terms of both accuracy and efficiency. In future work, we hope to extend our method to more natural grammars like conjunctive languages, TAG, LCFRS and other mildly context-sensitive languages.

Syntax correction tools should be as user-friendly and widely-accessible as autocorrection tools in word processors. From a practical standpoint, we argue it is possible to reduce disruption from manual syntax repair and improve the efficiency of working programmers by driving down the latency needed to synthesize an acceptable repair. In contrast with program synthesizers that require intermediate editor states to be well-formed, our synthesizer does not impose any constraints on the code itself being written and can be used in a live programming environment.

The design of the tool itself is relatively simple. Tidyparse accepts a context-free language and a string. If the string is valid, it returns the parse forest, otherwise, it returns a set of repairs, ordered by likelihood. This approach has many advantages, enabling us to repair broken syntax, correct typos and recover from small errors, while being provably sound and complete with respect to the grammatical specification and a Levenshtein bound. It is also compatible with neural program synthesis and repair techniques, which can be used to score and rank the generated repairs.

We have implemented our approach as an IDE plugin and demonstrated its viability as a practical tool for realtime programming. A considerable amount of effort was devoted to supporting fast error correction functionality. Tidyparse is capable of generating repairs for invalid code in a range of practical languages with very little downstream language integration required. We plan to continue expanding its grammar and autocorrection functionality to cover a broader range of languages and hope to conduct a more thorough user study to validate its effectiveness.

DATA-AVAILABILITY STATEMENT

An artifact for Tidyparse is currently available as a browser application. [5] While the browser demo is current single-threaded and does not support ranking repairs by naturalness, it is capable of automatically suggesting repairs to syntax errors in context-free languages. The data and source code for the experiments in this paper will be made available upon publication.

A EXAMPLE REPAIRS

Below, we provide a few representative examples of broken code snippets and the corresponding human repairs that were successfully ranked first by our method. On the left is a complete snippet fed to the model and on the right, the corresponding human repair that was correctly predicted.

Original broken code	First predicted repair

`form sympy import *`
`x = Symbol('x', real=True)`
`x, re(x), im(x)`
	`from sympy import *`
	`x = Symbol('x', real=True)`
	`x, re(x), im(x)`

`result = yeald From(item.create())` `raise Return(result)`	`result = yield From(item.create())` `raise Return(result)`
`df.apply(lambda row: list(set(row['ids'])))`	`df.apply(lambda row: list(set(row['ids'])))`
`sum(len(v) for v items.values()))`	`sum(len(v) for v in items.values())`

`def average(values):`
`  if values == (1,2,3):`
`  return (1+2+3)/3`
`  else if values == (-3,2,8,-1):`
`  return (-3+2+8-1)/4`
	`def average(values):`
	`  if values == (1,2,3):`
	`  return (1+2+3)/3`
	`  elif values == (-3,2,8,-1):`
	`  return (-3+2+8-1)/4`

`dict = {`
`  "Jan": 1`
`  "January": 1`
`  "Feb": 2 # and so on`
`}`
	`dict = {`
	`  "Jan": 1,`
	`  "January": 1,`
	`  "Feb": 2 # and so on`
	`}`

`class MixIn(object)`
`  def m():`
`  pass`
 	
`class classA(MixIn):`
 	
`class classB(MixIn):`
	`class MixIn(object):`
	`  def m():`
	`  pass`
	
	`class classA(MixIn): pass`
	
	`class classB(MixIn): pass`

B RAW DATA

Raw data from Precision@k experiments across snippet length and Levenshtein distance from § 6.2. $|\sigma|$ indicates the snippet length and Δ indicates the Levenshtein distance between the broken and code and human fix computed over lexical tokens. For Tidyparse, we sample until exhausting the admissible set or a timeout of 30s is reached, whichever happens first, then rank the results. For the other models Precision@1, we sample one repair and report the percentage of repairs matching the human repair. For Precision@All, we report the percentage of repairs matching the human repair within the top 20000 samples.

C SUPPLEMENTAL PROOFS

The problem of syntax error correction under a finite number of typographic errors is reducible to the bounded Levenshtein-CFL reachability problem, which can be formally stated as follows:

Definition C.1. The language edit distance (LED) is the minimum number of edits required to transform an invalid string into a valid one, where validity is defined as containment in a context-free language, $\ell : \mathcal{L}$, i.e., $\Delta^*(\underset{\sim}{\sigma}, \ell) \coloneqq \min_{\sigma \in \ell} \Delta(\underset{\sim}{\sigma}, \sigma)$, and Δ is the Levenshtein distance.

We seek to find the set of strings S such that $\forall \sigma' \in S, \Delta(\underset{\sim}{\sigma}, \sigma') \leq q$, where q is greater than or equal to the language edit distance. We call this set the *Levenshtein ball* of $\underset{\sim}{\sigma}$ and denote it $\Delta_q(\underset{\sim}{\sigma})$. Since $1 \leq \Delta^*(\underset{\sim}{\sigma}, \ell) \leq q$, we have $1 \leq q$. We now consider an upper bound on $\Delta^*(\underset{\sim}{\sigma}, \ell)$, i.e., the greatest lower bound on q such that $\Delta_q(\underset{\sim}{\sigma}) \cap \ell \neq \varnothing$.

Lemma C.2. *For any nonempty language $\ell : \mathcal{L}$ and invalid string $\underset{\sim}{\sigma} : \Sigma^n \cap \bar{\ell}$, there exists an (σ', m) such that $\sigma' \in \ell \cap \Sigma^m$ and $0 < \Delta(\underset{\sim}{\sigma}, \ell) \leq \max(m, n) < \infty$.*

Proof. Since ℓ is nonempty, it must have at least one inhabitant $\sigma \in \ell$. Let σ' be the smallest such member. Since σ' is a valid sentence in ℓ, by definition it must be that $|\sigma'| < \infty$. Let $m \coloneqq |\sigma'|$. Since we know $\underset{\sim}{\sigma} \notin \ell$, it follows that $0 < \Delta(\underset{\sim}{\sigma}, \ell)$. Let us consider two cases, either $\sigma' = \varepsilon$, or $0 < |\sigma'|$:

- If $\sigma' = \varepsilon$, then $\Delta(\underset{\sim}{\sigma}, \sigma') = n$ by full erasure of $\underset{\sim}{\sigma}$, or
- If $0 < m$, then $\Delta(\underset{\sim}{\sigma}, \sigma') \leq \max(m, n)$ by overwriting.

In either case, it follows $\Delta(\underset{\sim}{\sigma}, \ell) \leq \max(m, n)$ and ℓ is always reachable via a finite nonempty set of Levenshtein edits, i.e., $0 < \Delta(\underset{\sim}{\sigma}, \ell) < \infty$. □

Let us now consider the maximum growth rate of the *admissible set*, $A \coloneqq \Delta_q(\underset{\sim}{\sigma}) \cap \ell$, as a function of q and n. Let $\bar{\ell} \coloneqq \{\underset{\sim}{\sigma}\}$. Since $\bar{\ell}$ is finite and thus regular, $\ell = \Sigma^* \setminus \{\underset{\sim}{\sigma}\}$ is regular by the closure of regular languages under complementation, and thus context-free a fortiori. Since ℓ accepts every string except $\underset{\sim}{\sigma}$, it represents the worst CFL in terms of asymptotic growth of A.

Lemma C.3. *The complexity of enumerating A is upper bounded by $\mathcal{O}\left(\sum_{c=1}^{q} \binom{cn+n+c}{c} (|\Sigma| + 1)^c\right)$.*

Proof. We can overestimate the size of A by considering the number of unique ways to insert, delete, or substitute c terminals into a string $\underset{\sim}{\sigma}$ of length n. This can be overaproximated by interleaving ε^c around every token, i.e., $\underset{\sim}{\sigma}_\varepsilon \coloneqq (\varepsilon^c \underset{\sim}{\sigma}_i)_{i=1}^n \varepsilon^c$, where $|\underset{\sim}{\sigma}_\varepsilon| = cn + n + c$, and only considering substitution. We augment $\Sigma_\varepsilon \coloneqq \Sigma \cup \{\varepsilon\}$ so that deletions and insertions may be treated as special cases of substitution. Thus, we have $cn + n + c$ positions to substitute ($|\Sigma_\varepsilon|$) tokens, i.e., $\binom{cn+n+c}{c}|\Sigma_\varepsilon|^c$ ways to edit $\underset{\sim}{\sigma}_\varepsilon$ for each $c \in [1, q]$. This upper bound is not tight, as overcounts many identical edits w.r.t. $\underset{\sim}{\sigma}$. Nonetheless, it is sufficient to show $|A| < \sum_{c=1}^{q} \binom{cn+n+c}{c}|\Sigma_\varepsilon|^c$. □

We note that the above bound applies to all strings and languages, and relates to the Hamming bound on $H_q(\underset{\sim}{\sigma}_\varepsilon)$, which only considers substitutions. In practice, much tighter bounds may be obtained by considering the structure of ℓ and $\underset{\sim}{\sigma}$. For example, based on an empirical evaluation from a dataset of human errors and repairs in Python code snippets ($|\Sigma| = 50, |\underset{\sim}{\sigma}| < 40, \Delta(\underset{\sim}{\sigma}, \ell) \in [1, 3]$), we estimate the *filtration rate*, i.e., the density of the admissible set relative to the Levenshtein ball, $D = |A|/|\Delta_q(\underset{\sim}{\sigma})|$ to have empirical mean $E_\sigma[D] \approx 2.6 \times 10^{-4}$, and variance $\mathrm{Var}_\sigma[D] \approx 3.8 \times 10^{-7}$.
