Jin Guo McGill University jguo@cs.mcgill.ca Xujie Si McGill University xsi@cs.mcgill.ca

Abstract

Tidyparse is a program synthesizer that performs real-time error correction for context free languages. Given both an arbitrary context free grammar (CFG) and an invalid string, the tool lazily generates admissible repairs while the author is typing, ranked by Levenshtein edit distance. Repairs are guaranteed to be complete, grammatically consistent and minimal. Tidyparse is the first system of its kind offering these guarantees in a real-time editor. To accelerate code completion, we design and implement a novel incremental parser-synthesizer that transforms CFGs onto a dynamical system over finite field arithmetic, enabling us to suggest syntax repairs in-between keystrokes. We have released an IDE plugin demonstrating the system described.*

1 Introduction

Modern research on error correction can be traced back to the early days of coding theory, when researchers designed *error-correcting codes* (ECCs) to denoise transmission errors induced by external interference, whether due to collision with a high-energy proton, manipulation by an adversary or some typographical mistake. In this context, *code* can be any logical representation for communicating information between two parties (such as a human and a computer), and an ECC is a carefully-designed code which ensures that even if some portion of the message should be corrupted through accidental or intentional means, one can still recover the original message by solving a linear system of equations. In particular, we frame our work inside the context of errors arising from human factors in computer programming.

In programming, most such errors initially manifest as syntax errors, and though often cosmetic, manual repair can present a significant challenge for novice programmers. The ECC problem may be refined by introducing a language, $\mathcal{L} \subset \Sigma^*$ and considering admissible edits transforming an arbitrary string, $s \in \Sigma^*$ into a string, $s' \in \mathcal{L}$. Known as *errorcorrecting parsing* (ECP), this problem was well-studied in the early parsing literature, cf. Aho and Peterson [1], but fell out of favor for many years, perhaps due to its perceived complexity. By considering only minimal-length edits, ECP can be reduced to the so-called *language edit distance* (LED) problem, recently shown to be subcubic [2], suggesting its possible tractability. Previous results on ECP and LED were primarily of a theoretical nature, but now, thanks to our contributions, we have finally realized a practical prototype.

2 Prior work

Prior work in this area follows two main streams. Kats [7] and deJong [5] and Diekmann [6] investigate error repair in LR grammars and more recently, Raselimo and Fischer use spectrum-based fault localization techniques [10]. Our approach can handle a more general class of context-free and bounded context-sensitive grammars and has a more theoretically rigorous grounding in language reachability [9]. Consequently, it is much simpler and can scaled up using a GPU. Tradeoffs exist as usual, which are discussed in Sec. 11.

3 Toy Example

Suppose we are given the following context free grammar:

For reasons that will become clear in the following section, this is automatically rewritten into the equivalent grammar:

```
F.! \rightarrow ! \epsilon+ \rightarrow \epsilon S \rightarrow false F.and \rightarrow and F.(\rightarrow ( \epsilon+ \rightarrow \epsilon+ \epsilon+ S \rightarrow F.! S S.) \rightarrow S F.) F.) \rightarrow S \rightarrow S or.S or.S \rightarrow F.or S F.\epsilon \rightarrow \epsilon S \rightarrow true S \rightarrow S and.S and.S \rightarrow F.and S F.or \rightarrow or S \rightarrow S \epsilon+ S \rightarrow F.(S.)
```

Given a string containing holes such as the one below, Tidyparse will return several completions in a few milliseconds:

```
true or ! ( false or ( <S> ) or ! <S> ) or <S>
true or ! ( false and ( <S> ) or ! <S> ) or <S>
```

```
true or ! (false and ( <S> ) and ! <S> ) or <S> true or ! (false and ( <S> ) and ! <S> ) and <S> ...

Similarly, if provided with a string containing various errors,
```

Similarly, if provided with a string containing various errors, Tidyparse will return several suggestions how to fix it, where green is insertion, orange is substitution and red is deletion.

```
1.) true and ( false or ! true )
2.) true and ( false or ! true )
3.) true and ( false or ( true ) )
...
```

In the following paper, we will describe how we built it.

9.) true and (false or ! <S>) and true false

 $^{^*}https://plugins.jetbrains.com/plugin/19570\text{-}tidyparse$

4 Matrix Theory

Recall that a CFG is a quadruple consisting of terminals (Σ) , nonterminals (V), productions $(P: V \to (V \mid \Sigma)^*)$, and a start symbol, (S). It is a well-known fact that every CFG is reducible to *Chomsky Normal Form*, $P': V \to (V^2 \mid \Sigma)$, in which every production takes one of two forms, either $w \to xz$, or $w \to t$, where w, x, z: V and $t: \Sigma$. For example, the CFG, $P:=\{S \to SS \mid (S) \mid ()\}$, corresponds to the CNF:

$$P' = \{ S \rightarrow QR \mid SS \mid LR, L \rightarrow (R \rightarrow), Q \rightarrow LS \}$$

Given a CFG, $\mathcal{G}': \langle \Sigma, V, P, S \rangle$ in CNF, we can construct a recognizer $R: \mathcal{G}' \to \Sigma^n \to \mathbb{B}$ for strings $\sigma: \Sigma^n$ as follows. Let 2^V be our domain, 0 be \varnothing , \oplus be \cup , and \otimes be defined as:

$$X \otimes Z := \left\{ w \mid \langle x, z \rangle \in X \times Z, (w \to xz) \in P \right\}$$
 (1)

If we define $\sigma_r^{\uparrow} := \{ w \mid (w \to \sigma_r) \in P \}$, then initialize $M_{r+1=c}^0(\mathcal{G}', e) := \sigma_r^{\uparrow}$ and solve for the fixpoint $M^* = M + M^2$,

$$M^0 := \begin{pmatrix} \varnothing & \sigma_1^{\rightarrow} & \varnothing & \cdots & \varnothing \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & \ddots \\ & \ddots & \ddots & \ddots & \ddots \\ \vdots & \ddots & \ddots &$$

we obtain the recognizer, $R(\mathcal{G}', \sigma) := S \in \Lambda_{\sigma}^*$? $\Leftrightarrow \sigma \in \mathcal{L}(\mathcal{G})$?

This decision procedure can be abstracted by lifting into the domain of bitvector variables, producing an algebraic expression for each scalar inhabitant of the northeasternmost bitvector Λ_{σ}^* , whose solutions correspond to valid parse forests for an incomplete string on the superdiagonal. Note that $\bigoplus_{c=1}^n M_{r,c} \otimes M_{c,r}$ has cardinality bounded by |V| and is thus representable as a fixed-length vector using the characteristic function, $\mathbb{1}$. In particular, \oplus , \otimes are redefined as \boxplus , \boxtimes over bitvectors so the following diagram commutes, †

$$\begin{array}{c} \langle \mathcal{G}', \ \Sigma^{n-1} \rangle & \text{Set} & \text{Bit} & \langle \mathcal{G}', \Sigma^{n-1} \rangle & \text{SAT} \\ \text{Rubix} & M \times M \xleftarrow{1^{2^{n \times n}}} & \mathbb{Z}_2^{|V|^{n \times n}} \times \mathbb{Z}_2^{|V|^{n \times n}} \times \mathbb{Z}_2^{|V|^{n \times n}} & \stackrel{\varphi^{2^{n \times n}}}{\longrightarrow} \mathcal{M} \times \mathcal{M} \\ & \oplus \otimes & + * & & & & & & & & \\ \text{Matrix} & 2^V \times 2^V \xleftarrow{1^2} & \mathbb{Z}_2^{|V|} \times \mathbb{Z}_2^{|V|} \times \mathbb{Z}_2^{|V|} \times \stackrel{\varphi^2}{\longrightarrow} \mathcal{V} \times \mathcal{V} \\ & \oplus \otimes & & \oplus \otimes & & & & & & & \\ \text{Vector} & 2^V \xleftarrow{1} & \mathbb{Z}_2^{|V|} \times \mathbb{Z}_2^{|V|} \times \stackrel{\varphi}{\longrightarrow} \stackrel{\varphi^2}{\longrightarrow} \mathcal{V} \times \mathcal{V} \end{array}$$

where $\mathcal V$ is a function $\mathbb Z_2^{|\mathcal V|} \to \mathbb Z_2$. Note that while always possible to encode $\mathbb Z_2^{|\mathcal V|} \to \mathcal V$ using the identity function, φ^{-1} may not exist, as an arbitrary $\mathcal V$ might take on zero, one, or in general, multiple solutions in $\mathbb Z_2^{|\mathcal V|}$.

Full details of the bisimilarity between parsing and matrix multiplication can be found in Valiant [11], who shows its

time complexity to be $\mathcal{O}(n^{\omega})$ where ω is the matrix multiplication bound ($\omega < 2.77$), and Lee [8], who shows that speedups to Boolean matrix multiplication are realizable by CFL parsers. Assuming sparsity, this technique is typically linearithmic, and we show it to be highly efficient in practice.

4.1 Context-sensitive reachability

It is well-known that the family of CFLs is not closed under intersection. For example, consider $\mathcal{L}_{\cap} := \mathcal{L}(\mathcal{G}_1) \cap \mathcal{L}(\mathcal{G}_1)$:

$$P_1 := \left\{ \begin{array}{ll} S \to LR, & L \to ab \mid aLb, & R \to c \mid cR \end{array} \right\}$$

$$P_2 := \left\{ \begin{array}{ll} S \to LR, & R \to bc \mid bRc, & L \to a \mid aL \end{array} \right\}$$

Note that \mathcal{L}_{\cap} generates the language $\{a^db^dc^d \mid d > 0\}$, which according to the pumping lemma is not context-free. We can encode $\bigcap_{i=1}^c \mathcal{L}(\mathcal{G}_i)$ as a polygonal prism with upper-triangular matrices adjoined to each rectangular face. More precisely, we intersect all terminals $\Sigma_{\cap} := \bigcap_{i=1}^c \Sigma_i$, then for each $t_{\cap} \in \Sigma_{\cap}$ and CFG, construct an equivalence class $E(t_{\cap}, \mathcal{G}_i) = \{w_i \mid (w_i \to t_{\cap}) \in P_i\}$ and bind them together:

$$\bigwedge_{t \in \Sigma_{\cap}} \bigwedge_{j=1}^{c-1} \bigwedge_{i=1}^{|\sigma|} E(t_{\cap}, \mathcal{G}_j) \equiv_{\sigma_i} E(t_{\cap}, \mathcal{G}_{j+1})$$
 (2)

Figure 1. Orientations of a $\bigcap_{i=1}^4 \mathcal{L}(\mathcal{G}_i) \cap \Sigma^6$ configuration. As $c \to \infty$, this shape approximates a circular cone whose symmetric axis joins σ_i with orthonormal unit productions $w_i \to t_{\cap}$, and $S_i \in \Lambda_{\sigma}^*$? represented by the outermost bitvector inhabitants. Equations of this form are equiexpressive with the family of CSLs realizable by finite CFL intersection.

4.2 Encoding CFG parsing as SAT solving

By allowing the matrix M^* to contain bitvector variables representing holes in the string and nonterminal sets, we obtain a set of multilinear equations over \mathbb{Z}_2 , whose solutions exactly correspond to the set of admissible repairs and their corresponding parse forests. Specifically, the repairs coincide with holes in the superdiagonal $M^*_{r+1=c}$, and the parse forests occur along the upper-triangular entries $M^*_{r+1< c}$.

$$M^* = \begin{pmatrix} \varnothing & \sigma_1^{\uparrow} & \mathcal{L}_{1,3} & \mathcal{L}_{1,3} & \mathcal{V}_{1,4} & \cdots & \mathcal{V}_{1,n} \\ & & \sigma_2^{\uparrow} & \mathcal{L}_{2,3} & & & & \\ & & & & \sigma_3^{\uparrow} & & & \\ & & & & & \mathcal{V}_{4,4} & & \\ & & & & & & \mathcal{V}_{n,n} \\ & & & & & & & \varnothing \end{pmatrix}$$
(3)

[†]Hereinafter, we use gray highlighting to distinguish between expressions containing only constants from those which may contain free variables.

Depicted above is a SAT tensor representing $\sigma_1 \sigma_2 \sigma_3$ _ . . . _ where shaded regions demarcate known bitvector literals $\mathcal{L}_{r,c}$ (i.e., representing established nonterminal forests) and unshaded regions correspond to bitvector variables $V_{r,c}$ (i.e., representing seeded nonterminal forests to be grown). Since $\mathcal{L}_{r,c}$ are fixed, we precompute them outside the SAT solver.

Gradient estimation

Now that we have a reliable method to fix *localized* errors, $S: \mathcal{G} \times (\Sigma \cup \{\varepsilon, \bot\})^n \to \{\Sigma^n\} \subseteq \mathcal{L}_{\mathcal{G}}$, given some unparseable string, i.e., $\sigma_1 \dots \sigma_n : \Sigma^n \cap \mathcal{L}(\mathcal{G})^c$, where should we put holes to obtain a parseable $\sigma' \in \mathcal{L}(\mathcal{G})$? One way to do so is by sampling repairs, $\sigma \sim \Sigma^{n \pm q} \cap \Delta_{\alpha}(\sigma)$ from the Levenshtein q-ball centered on σ , i.e., the space of all admissible edits with Levenshtein distance $\leq q$, loosely analogous to a finite difference approximation. To admit variable-length edits, we first add an ε^+ -production to each unit production:

$$\frac{\mathcal{G} \vdash \varepsilon \in \Sigma}{\mathcal{G} \vdash (\varepsilon^{+} \to \varepsilon \mid \varepsilon^{+} \varepsilon^{+}) \in P} \varepsilon\text{-DUP}$$

$$\frac{\mathcal{G} \vdash (A \to B) \in P}{\mathcal{G} \vdash (A \to B \varepsilon^{+} \mid \varepsilon^{+} B \mid B) \in P} \varepsilon^{+}\text{-INT}$$

Next, suppose $U:\mathbb{Z}_2^{m\times m}$ is a matrix whose structure is shown in Eq. 4, wherein C is a primitive polynomial over \mathbb{Z}_2^m with coefficients $C_{1...m}$ and semiring operators $\oplus := \veebar, \otimes := \land$:

$$U^{t}V = \begin{pmatrix} C_{1} & \cdots & C_{m} \\ T & \circ & \cdots & \circ \\ \circ & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \vdots \\ \circ & \cdots & \circ & T & \circ \end{pmatrix}^{t} \begin{pmatrix} V_{1} \\ \vdots \\ \vdots \\ V_{m} \end{pmatrix}$$
(4)

Since C is primitive, the sequence $S = (U^{0...2^m-1}V)$ must have full periodicity, i.e., for all $i, j \in [0, 2^m)$, $S_i = S_j \implies i = j$. To uniformly sample σ without replacement, we first form an injection $\mathbb{Z}_2^m \rightharpoonup \binom{n}{d}^\dagger \times \Sigma_{\varepsilon}^{2d}$ using a combinatorial number system, cycle over S, then discard samples which have no witness in $\binom{n}{d} \times \Sigma^{2d}_{\varepsilon}$. This method requires $\widetilde{\mathcal{O}}(1)$ per sample and $\widetilde{\mathcal{O}}\left(\binom{n}{d}|\Sigma+1|^{2d}\right)$ to exhaustively search $\binom{n}{d}\times\Sigma_{\varepsilon}^{2d}$. Finally, to sample $\sigma\sim\Delta_q(\sigma)$, we enumerate templates

 $H(\sigma, i) = \sigma_{1...i-1} _ \sigma_{i+1...n}$ for each $i \in \cdot \in {n \brace d}$ and $d \in 1...q$, then solve for \mathcal{M}_{σ}^* . If $S \in \Lambda_{\sigma}^*$? has a solution, each edit in each $\sigma' \in \sigma$ will match one of the following seven patterns:

$$\begin{aligned} \text{Deletion} &= \left\{ \ldots \sigma_{i-1} \ \underset{1}{\forall_1} \ \underset{2}{\forall_2} \ \sigma_{i+1} \ldots \ \underset{1,2}{\forall_{1,2}} = \varepsilon \right. \\ \text{Substitution} &= \left\{ \ldots \sigma_{i-1} \ \underset{1}{\forall_1} \ \underset{2}{\forall_2} \ \sigma_{i+1} \ldots \ \underset{1}{\forall_1} \ \varepsilon \wedge \gamma_2 = \varepsilon \right. \\ \left. \ldots \sigma_{i-1} \ \underset{1}{\forall_1} \ \underset{2}{\forall_2} \ \sigma_{i+1} \ldots \ \underset{1}{\forall_1} = \varepsilon \wedge \gamma_2 \neq \varepsilon \right. \\ \left. \ldots \sigma_{i-1} \ \underset{1}{\forall_1} \ \underset{2}{\forall_2} \ \sigma_{i+1} \ldots \ \underset{1}{\forall_1} \ \underset{2}{\forall_2} \cap \left\{ \varepsilon, \sigma_i \right\} = \varnothing \\ \\ \left. \ldots \sigma_{i-1} \ \underset{1}{\forall_1} \ \underset{2}{\forall_2} \ \sigma_{i+1} \ldots \ \underset{1}{\forall_1} = \sigma_i \wedge \gamma_2 \notin \left\{ \varepsilon, \sigma_i \right\} \\ \left. \ldots \sigma_{i-1} \ \underset{1}{\forall_1} \ \underset{2}{\forall_2} \ \sigma_{i+1} \ldots \ \underset{1}{\forall_1} \notin \left\{ \varepsilon, \sigma_i \right\} \wedge \gamma_2 = \sigma_i \\ \left. \ldots \sigma_{i-1} \ \underset{1}{\forall_1} \ \underset{2}{\forall_2} \ \sigma_{i+1} \ldots \ \gamma_{1,2} = \sigma_i \right. \end{aligned}$$

$$\uparrow \text{Where} \left\{ \underset{d}{^n} \right\} \text{ is used to denote the set of all } d\text{-element subsets of} \left\{ 1, \ldots, n \right\}.$$

Adaptive Sampling

Since there are $\Sigma_{d=1}^q \binom{n}{d}$ sketch templates in total, each with $(|\Sigma|+1)^{2d}$ possible repairs, if *n* and *q* are large, this space can be intractable to search through exhaustively and a uniform prior may be highly sample-inefficient. In order to facilitate real-time assistance, we prioritize likely repairs according to the following four-step procedure:

- 1. Retrieve the most recent \mathcal{G} and σ from the editor.
- 2. Lazily enumerate $\binom{n}{d}$ for increasing values of $d \ge 1$.
- 3. Draw $\sigma \sim \Sigma^{n \pm q} \cap \Delta_q(\sigma)$ sans replacement using 4.3.
- 4. Decode and rerank models by Levenshtein distance.

For example, suppose we have $\sigma : \Sigma^{90}$, and a probability distribution over all possible edits. This distribution, which we call \mathcal{F} , is then used to prioritize admissible repairs. Reprojected onto σ , the distribution \mathcal{F} might appear thusly:

Figure 2. The distribution \mathcal{F} , reprojected onto the invalid string yields a set of edit locations likely to contain admissible repairs, from which we draw subsets of size *d*.

Morally, we would prefer sketch templates and repairs which are "natural", i.e., more likely to be accepted by a human programmer over those which are not. To do so, we draw holes and rank admissible repairs using a distance metric over the Levenshtein q-ball, $\Delta_q(\underline{\sigma})$. One such metric, the Kantorovich–Rubinstein (KR) metric, δ_{KR} , can be viewed as an optimal transport problem minimizing $\Pi(\mu, \nu)$, the set of all mass-conserving transportation plans between two probability distributions μ and ν over some metric space Ω:

$$\delta_{\mathrm{KR}}(\mu,\nu) := \inf_{\pi \in \Pi(\mu,\nu)} \int_{\mathcal{O} \times \mathcal{O}} \delta(x,y) d\pi(x,y) \tag{5}$$

More specifically in our setting, Ω is a discrete product space that factorizes into (1) the specific edit locations (e.g., informed by caret position, historical edit locations, or a static analyzer), (2) probable completions (e.g., from a Markov chain or neural language model) and (3) an associated cost model, $C:(\Sigma^* \times \Sigma^*) \to \mathbb{R}$, which can be any number of suitable distance metrics, such as language edit distance, finger travel distance on a physical keyboard in the case of typo correction, weighted Levenshtein distance, or stochastic contextual edit distance [4] in the case of probabilistic edits. Our goal then is to discover repairs which minimize $C(\sigma, \sigma')$, subject to the grammar and latency constraints.

6 Error Recovery

Not only is Tidyparse capable of suggesting repairs to invalid strings, it can also return partial trees for those strings, which is often helpful for debugging purposes. Unlike LL- and LR-style parsers which require special rules for error recovery, Tidyparse can simply analyze the structure of M^* to recover partial subtrees. If $S \notin \Lambda_\sigma^*$, the upper triangular entries of M^* will take the form of a jagged-shaped ridge whose peaks indicate the roots of maximally-parsable substrings $\hat{\sigma}_{i,j}$.

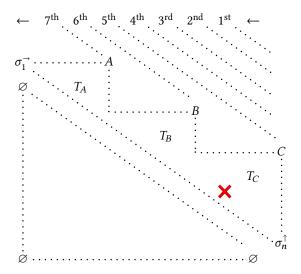

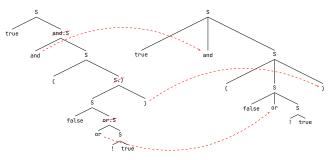

Figure 3. Peaks along the UT matrix ridge correspond to maximally parseable substrings. By recursing over upper diagonals of decreasing elevation and discarding all subtrees that fall under the shadow of another's canopy, we can recover the partial subtrees. The example depicted above contains three such branches, rooted at nonterminals *C*, *B*, *A*.

These branches correspond to peaks on the upper triangular (UT) matrix ridge. As depicted in Fig. 3, we traverse the peaks by decreasing elevation to collect partial AST branches.

7 Tree Denormalization

Our parser emits a binary forest consisting of parse trees for the candidate string according to the CNF grammar, however this forest contains many so-called *Krummholz*, or *flag trees*, often found clinging to windy ridges and mountainsides.

Pre-Denormalization

Post-Denormalization

Algorithm 1 Rewrite procedure for tree denormalization

```
procedure Denormalize(t: Tree)

stems ← { Denormalize(c) | c ∈ t.children } 

if t.root ∈ V_{\mathcal{G}'} \setminus V_{\mathcal{G}} then

return stems > Drop synthetic nonterminals.

else > Graft the denormalized children on root.

return { Tree(root, stems) } 

end if 
end procedure
```

To recover a parse tree congruent with the user-specified grammar, we prune all synthetic nodes and graft their stems onto the grandparent via a simple recursive procedure (Alg. 1).

8 Practical Example

Tidyparse accepts any context-free grammar – this can be either provided by the user or ingested from a BNF-like specification. The following is a slightly more complex grammar, designed to approximate the OCaml grammar. We use the ––– delimiter to separate the grammar from the example:

```
S -> A | V | ( X , X ) | X X | ( X )
A -> Fun | F | L | L in X
Fun -> fun V `->` X
F -> if X then X else X
L -> let V = X | let rec V = X
V -> Vexp | ( Vexp ) | Vexp Vexp
Vexp -> VarName | FunName | Vexp V0 Vexp
Vexp -> ( VarName , VarName ) | Vexp Vexp
VarName -> a | b | c | d | e | ... | z
FunName -> foldright | map | filter
V0 -> + | - | * | / | > | = | < | `||` | &&
---
let curry f = ( fun x y -> f ( _ _ _ ___) )
```

```
let curry f = ( fun x y -> f ( <X> ) )
let curry f = ( fun x y -> f ( <FunName> ) )
let curry f = ( fun x y -> f ( curry <X> ) )
...
```

8.1 Context-sensitive languages

Many programming languages exhibit either lexical or syntactic context-sensitivity, e.g., Python indentation. Tidyparse can analyze such languages using finite CFL-intersection, allowing it to generalize to a broader family of languages:

8.2 Grammar Assistance

Tidyparse uses a CFG to parse the CFG, so it can provide assistance while the user is designing the CFG. For example, if the CFG does not parse, it will suggest possible fixes. In the future, we intend to use this functionality to perform example-based codesign and grammar induction.

```
B -> true | false |

B -> true | false |

B -> true | false |

RHS>

B -> true | false | <RHS>

...
```

8.3 Interactive Nonterminal Expansion

Users can interactively build up a complex expression by placing the caret over a placeholder they wish to expand,

```
if <Vexp> X then <Vexp> else <Vexp>
```

then invoking Tidyparse by pressing ctrl + Space, to receive a list of expressions consistient with the grammar:

```
if map X then <Vexp> else <Vexp>
if uncurry X then <Vexp> else <Vexp>
if foldright X then <Vexp> else <Vexp>
...
```

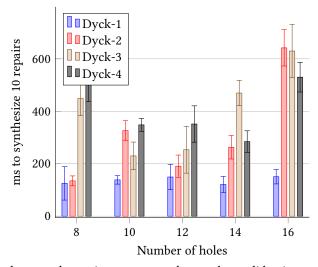

9 Latency Benchmark

In the following benchmarks, we measure the wall clock time required to synthesize solutions to length-50 strings sampled from various Dyck languages, where Dyck-n is the Dyck language containing n types of balanced parentheses.

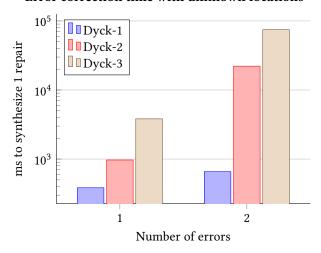

In the first experiment, we sample a random valid string $\sigma \sim \Sigma^{50} \cap \mathcal{L}_{Dyck-n}$, then replace a fixed number tokens with holes and measure the average time taken to decode ten syntactically-admissible repairs across 100 trial runs.

Error correction time with known locations

In the second experiment, we sample a random valid string as before, but delete p tokens at random and rather than provide the location(s), ask our model to solve for both the location(s) and repair by sampling uniformly from all n-token HCs, then measure the total time required to decode the first admissible repair. Note the the logarithmic scale on the y-axis.

Error correction time with unknown locations

10 Accuracy Benchmark

We analyze synthetic errors in Java and Python.
We also compare with the Break-it-fix-it (BIFI) dataset [12].

11 Discussion

While error correction with a few errors is tolerable, latency can vary depending on many factors including string length and grammar size. If errors are known to be concentrated in specific locations, such as the beginning or end of a string, then latency is typically below 500ms. Should errors occur uniformly at random, admissible repairs can take longer to discover, however these scenarios are unusual in our experience. We observe that errors are typically concentrated nearby historical edit locations, which can be retrieved from the IDE or version control. Further optimizations that reduce the total number of repairs checked are possible by eliminating improbable sketch templates.

Tidyparse in its current form has a number of technical shortcomings: firstly it does not incorporate any neural language modeling technology at present, an omission we hope to address in the near future. Training a language model to predict likely repair locations and rank admissible results could lead to lower overall latency and more natural repairs.

Secondly, our current method generates sketch templates using a naïve enumerative search, feeding them individually to the SAT solver, which has the tendency to duplicate prior work and introduces unnecessary thrashing. Considering recent extensions of Boolean matrix-based parsing to linear context-free rewriting systems (LCFRS) [3], it may be feasible to search through these edits within the SAT solver, leading to yet unrealized and possibly significant speedups.

Lastly and perhaps most significantly, Tidyparse does not incorporate any semantic constraints, so its repairs while syntactically admissible, are not guaranteed to be semantically valid. We note however, that it is possible to encode type-based semantic constraints into the solver and intend to explore this direction more fully in future work.

Although not intended to be a dedicated parser and we make no attempt to rigorously compare parsing latency, parsing valid strings with Tidyparse is typically competitive with classical parsing methods. Our primary motivation is to facilitate the usability and explainability of parsing with errors. We envision three primary use cases: (1) helping novice programmers become more quickly familiar with a new programming language (2) autocorrecting common typos among proficient but forgetful programmers and (3) as a prototyping tool for PL educators and designers.

Featuring a grammar editor and built-in SAT solver, Tidyparse helps developers navigate the language design space, visualize syntax trees, debug parsing errors and quickly generate simple examples and counterexamples for testing. Although the algorithm may seem esoteric at first glance, in our experience it is much more interpretable than classical parsers, which exhibit poor error-recovery and diagnostics.

12 Conclusion

Tidyparse accepts a CFG and a string to parse. If the string is valid, it returns the parse forest, otherwise, it returns a set of repairs, ordered by their Levenshtein edit distance to the invalid string. Our method compiles each CFG and candidate string onto a matrix dynamical system using an extended version of Valiant's construction and solves for its fixedpoints using an incremental SAT solver. This approach to parsing has many advantages, enabling us to repair syntax errors, correct typos and generate parse trees for incomplete strings. By allowing the string to contain holes, repairs can contain either concrete tokens or nonterminals, which can be manually expanded by the user or a neural-guided search procedure. From a theoretical standpoint, this technique is particularly amenable to neural program synthesis and repair, naturally integrating with the masked-language-modeling task (MLM) used by transformer-based neural language models.

From a practical standpoint, we have implemented our approach as an IDE plugin and demonstrated its viability as a tool for live programming. Tidyparse is capable of generating repairs for invalid code in a range of toy languages. We plan to continue expanding its grammar and autocorrection functionality to cover a broader range of languages and hope to conduct a more thorough user study to validate its effectiveness in the near future. Further examples can be found at our GitHub repository: https://github.com/breandan/tidyparse

13 Acknowledgements

The first author would like to thank his co-advisor Xujie Si for providing many helpful suggestions during the development of this project, including the optimized fixpoint, test cases, and tree denomalization procedure. In addition, the authors extend their thanks to Nghi Bui at FPT Software for early feedback on the IDE plugin, Zhixin Xiong for contributing the OCaml grammar, Brigitte Pientka for asking the crucial question, "Where do you put the holes?", and Ori Roth for providing helpful comments on an early draft of this paper.
